Patient height, weight and sex were recorded. MR imaging was performed with a Siemens Vision scanner operating at 1.5 T (tesla) with the patient supine. A phased array spine coil was used. The relevant anatomy was demonstrated most clearly using T2 sagittal plane images and consecutive T2 sagittal images of 0.44 cm thickness of the sacrum from the upper margin of S1 to the caudad limit of the sacral hiatus were therefore used (fig. 1). Using the Siemens computer software, measurements were made by two of the authors (I. M. C. and B. P. B.) using stored images for each patient on two separate occasions. If there was a discrepancy between measurements, a third measurement was made and the mean value recorded.

The length (fig. 2) and thickness (fig. 3) of the SCM (if present) were measured on the images giving the largest measurement. Only that part of the SCM through which the sacral canal could be entered with a needle, that is the length of the SCM with clearly visible underlying caudal space, was

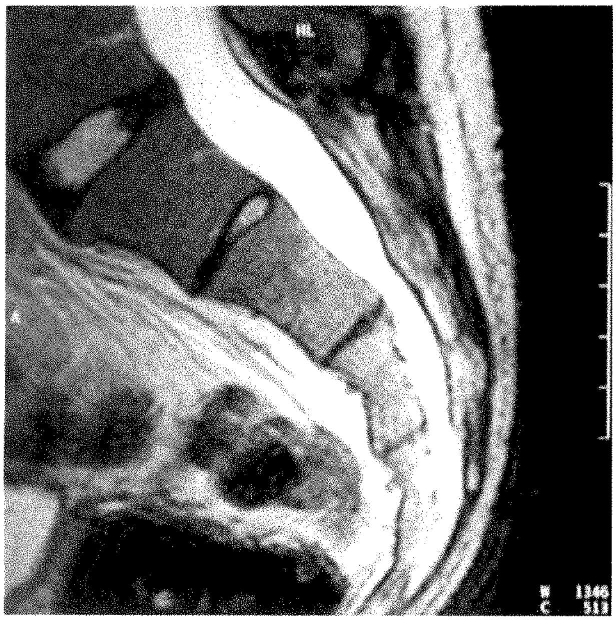

*Figure 1* T2 sagittal image of the sacrum and caudal space.

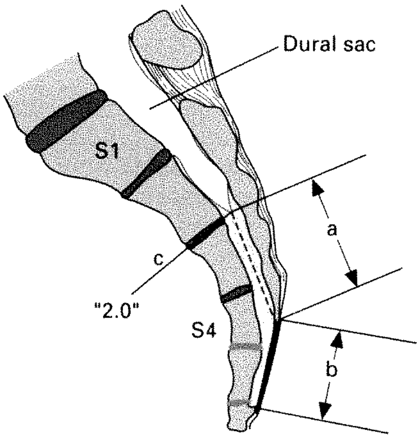

*Figure 2* Diagram of the sacrum and caudal space (using fig. 1 as a template) showing the shortest linear distance from the dura to the upper limit of the sacrococcygeal membrane (a), the length of the sacrococcygeal membrane (b) and the vertebral level of the caudal limit of the dura ("2.0", c).

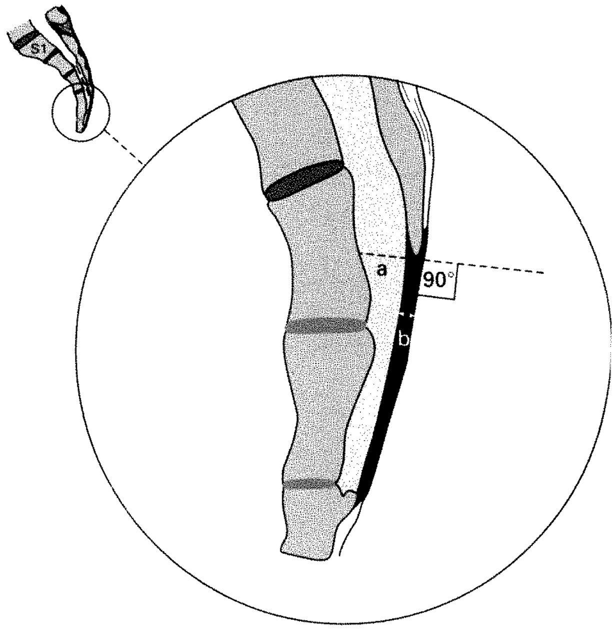

*Figure 3* Diagram of the sacrum and caudal space (using fig. 1 as a template) showing the maximum depth of the caudal space at 90° and adjacent to the sacrococcygeal membrane ("AP diameter", a) and the maximum width of the sacrococcygeal membrane (b).

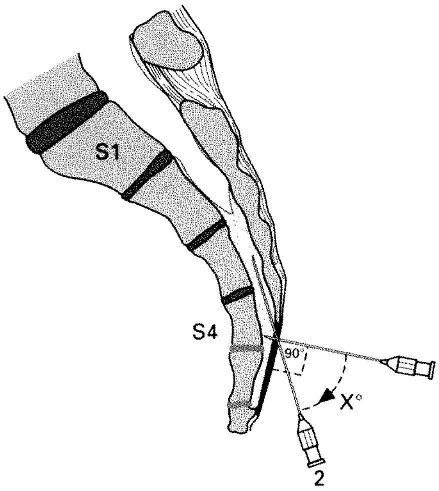

*Figure 4* Diagram of the best fit angle for needle insertion into the caudal space ($X^0$=angle of caudal depression of the needle from position 1 to position 2).

used for these measurements. The location of the upper limit of the SCM (corresponding to the apex of the sacral hiatus) in relation to the adjacent vertebral body was recorded. For example, "4.2" indicated that the upper limit of the SCM was adjacent to a position 4.2 vertebral bodies below the upper margin of the body of S1 (fig. 2). The maximum depth (AP diameter, fig. 3) of the caudal space at an angle of 90° to the SCM and its location in relation to the SCM (upper or middle third of the SCM) were also recorded. The best fit angle for needle insertion into the caudal space via the upper third of the SCM was determined (fig. 4). This position was described by measuring the angle of caudal depression required from a line drawn at 90° to the SCM. The location of the lowest limit of the dural sac in relation to the adjacent vertebral body (as above) and the shortest linear distance from the dura to the upper limit of the SCM were recorded (fig. 2). The volume of the sacral canal excluding the foraminae and the dural sac was estimated by obtaining the product of the sum of the areas of the sacral canal from each T2 sagittal plane image and 0.44 (thickness of each consecutive T2 sagittal image).

Data were analysed where appropriate using Student's *t* test and regression analysis. A probability of 0.05 or less was considered statistically significant.

## Results

We studied 23 females and 14 males (table 1). In one patient, height and weight were not recorded. In two patients the volume of the sacral canal could not be recorded because of poor reproducibility of results. Data from these patients were excluded from appropriate analyses. There were significant differences between the heights and weights of females

and males ($P$=0.001 and $P$<0.001, respectively). Table 2 gives the measurements of the SCM, sacral canal and position of the lower limit of the dural sac. Data were comparable for females and males except that the SCM was significantly thicker in females ($P$=0.005) and the volume of the sacral canal was significantly greater in males (16.5 *vs* 13.2 $cm^3$) ($P$=0.019). The relationships between sacral canal volume and height and sacral canal volume and weight are given by the regression equations: $y=-17.7+0.19x$ ($r^2=0.27$, $P=0.002$) and $y=5.76+0.12x$ ($r^2=0.33$, $P<0.001$), respectively. There was no relationship between age and sacral canal volume ($y=17.1-0.06x$, $r^2=0.07$, $P=0.142$).

## Discussion

Successful performance of a caudal block requires identification of the sacral hiatus, passage of a needle through the SCM and placement of the needle (or cannula) along the axis of the sacral canal without entering the dural sac or other structures. This may be technically difficult in adult patients. A detailed knowledge of the anatomy, dimensions and variations of the sacral region are therefore desirable to increase the reliability and safety of using this technique. This knowledge is based mainly on the results of post-mortem studies performed more than 50 yr ago. We were particularly interested to compare our findings with this previous work. Although the patients included in our study presented for investigation of back pain, most of their symptoms originated from the lumbar region of the spine and none had undergone previous spinal surgery or had evidence of a congenital abnormality. We therefore assumed that the anatomy of their sacral region would be representative of the general population.

In 33 patients the SCM was identified easily and measured. However, we were unable to identify a sacral hiatus and SCM on the MR scans in four (10.8%) of our patients. Although we cannot be certain of its absence without axial imaging, in most patients this would represent a clinically insurmountable obstacle when performing a caudal block. Although Trotter and Lanier found obliteration of the hiatus in some of the skeletons in their study, the incidence was not recorded.[5]

Trotter and Lanier[5] located the apex of the hiatus most commonly at the level of the lower third of the body of S4, although this varied greatly. We found the median and mode of the upper limit of the SCM to be at the level of the upper third of the body of S5, although there was also wide variation across two vertebral bodies. It would have been desirable to relate the site of the SCM to a palpable bony landmark such as the tip of the coccyx. However, the tip of the coccyx was not demonstrated clearly in many scans for technical reasons. Identification of other useful and palpable landmarks was also difficult as MR imaging was performed only in the sagittal plane. Our initial evaluation of axial imaging suggested that it added little to the information gained from the sagittal sections.

The mean length of the SCM in our study was

22.6 mm. This measurement was similar to the mean length of 26.3 mm obtained from a study of the "recent" anatomy of approximately 50 cadavers.[2] However, the upper ranges for the bony length of the sacral hiatus for males and females (60 and 65 mm, respectively), as measured by Trotter and Lanier in the sacra of 518 white Americans[5], were larger than for our males and females (31 and 36 mm, respectively). This may be related to our smaller sample size, measurement errors, population differences and almost certainly differences between living and post-mortem tissues.

The mean maximum AP diameter of the caudal space adjacent to the SCM for all of our patients was 4.6 mm. Trotter and Lanier found the mean maximum AP diameter to be 4.6 (SD 1.7; range 0–10) mm and 4.9 (1.5; 0–12) mm in white females and males, respectively.[5] These measurements were similar to our results, although we measured the AP diameter at an angle of 90° to the SCM. This small dimension may contribute to the anatomical difficulties encountered during caudal techniques. Also, Trotter and Lanier found that in 5% of subjects the AP diameter of the canal at the apex of the hiatus was <2 mm. We found only one patient with a diameter of less than 2 mm. Our female patients demonstrated a trend towards larger AP canal diameters ($P=0.078$). This latter observation may suggest that caudal techniques might be performed with less difficulty in female patients, although any differences are probably not clinically relevant. As the maximum canal diameter was found adjacent to the upper third of the SCM in most of our patients (95.5%), passage of a needle near the apex of the SCM might be expected to reduce difficulty in clinical practice.

A common technique for performing a caudal block is to insert the needle at an angle of 90° to the SCM until the ligament is penetrated, followed by depression of the needle until it is estimated that the shaft of the needle is in the plane of the sacral canal and then advancement along the canal.[6] Given the wide variation in sacral anatomy, it is understandably easy to misplace the needle in adults. Our findings suggest that successful needle placement is more likely if the needle is inserted at 90° to the SCM and then depressed in a caudal direction through an angle of approximately 55–60°. However, the variation in this angle must be taken into account.

Early anatomical studies suggested that the volume of the sacral canal (including the sacral foraminae) in adults was slightly more than 30 (range 12–65) ml.[7] However, this is the volume of dry bones and in life the canal is filled with the dural sac and its contents, nerves, blood vessels, fat and connective tissue. We estimated the mean volume of the sacral canal to be 14.4 (range 9.5–26.6) cm$^3$, a much smaller volume than that reported previously. This could be explained partly by our measurement not including the volume of the dural contents or the volume of the sacral foraminae. Relating our measurement of canal volume to clinical practice is difficult. However, when making clinical decisions as to the injectate volume necessary for particular caudal techniques, it should be noted that previous radio-opaque dye injection studies have demonstrated variable leakage from the canal through the sacral foraminae.[8] Furthermore, a relationship between age, height and the level of anaesthesia achieved with caudal extradural block has not been found[9] although this has been reported after lumbar extradural block.[10] Our study did, however, demonstrate some relationship between height and volume of the canal and weight and volume of the canal, although there was no relationship between age and volume.

Previous cadaver work has also shown wide variation in the position of the inferior extremity of the dura with a "mean" position adjacent to the middle third of the body of S2.[2] In our study, the median position was also at the middle third of S2.

We found the mean shortest distance from the dura to the upper limit of the SCM to be longer than previous post-mortem findings, although the ranges were similar (60.5 mm, range 34–80 mm *vs* 47.4 mm, range 19–75mm).[2] The lower dimensions of these ranges are most relevant to clinical practice as the length of the needle performing the caudal block must be chosen carefully so as to avoid puncturing the dura. A 21-gauge, 40-mm "green" needle is often used to perform a caudal block. If this needle were inserted fully into the caudal space, there would be some patients in whom dural puncture might occur. Even a 23-gauge "blue" needle with a length of 25 mm should be used with caution.

In summary, we suggest that to increase the chances of performing a successful caudal block with minimal risk of dural puncture, the needle or cannula should enter the SCM in its upper third at 90° followed by caudal depression through an angle of 55–60° and advancement along the canal no more than is necessary (remembering that the shortest distance to the dural sac ranges from 34 mm in our study and 19 mm in a previous study). An absent hiatus and SCM should be considered if the block proves difficult or impossible to perform.

# I.m. midazolam as premedication produces a concentration-dependent decrease in core temperature in male volunteers

T. MATSUKAWA, K. HANAGATA, M. OZAKI, H. IWASHITA, M. KOSHIMIZU AND T. KUMAZAWA

## Summary

We tested the hypothesis that premedication with i.m. midazolam decreases core temperature dose-dependently. We studied six male volunteers, in random order, on 3 days: (1) no midazolam administration (control day), (2) midazolam 0.025 mg $kg^{-1}$ i.m., (3) midazolam 0.075 mg $kg^{-1}$ i.m. On the first day, subjects were maintained alert during a 30-min control period. On the second and third days, midazolam 0.025 or 0.075 mg $kg^{-1}$ was administered i.m. Core temperatures were measured at the right tympanic membrane. Four adhesive skin surface probes were fixed on the chest, upper right arm, lateral calf and thigh. Finger tip perfusion was evaluated using forearm minus fingertip and calf minus toe, skin surface temperature gradients. Thirty minutes after midazolam i.m., the level of sedation in the volunteers was assessed. Peripheral venous blood was obtained immediately after the assessment of the level of sedation. Tympanic membrane temperatures after administration of midazolam 0.075 mg $kg^{-1}$ i.m. were significantly lower than those on the control and midazolam 0.025 mg $kg^{-1}$ i.m. days at 20 and 30 min. The decreases in tympanic membrane temperatures at 30 min after midazolam i.m. became larger as the volunteers were more deeply sedated. I.m. midazolam produced a concentration-dependent decrease in tympanic membrane temperature at 30 min after midazolam 0.025 and 0.075 mg $kg^{-1}$ i.m. We conclude that midazolam impaired tonic thermoregulatory vasoconstriction, allowing core-to-peripheral heat redistribution in a dose-dependent manner after i.m. administration. (*Br. J. Anaesth.* 1997; **78**: 396–399).

**Key words**
Hypnotics benzodiazepine, midazolam. Premedication, midazolam. Sedation. Temperature, effects. Temperature, monitoring.

Midazolam is a commonly used sedative and anaesthetic adjuvant and the first clinically used water-soluble benzodiazepine. Furthermore, midazolam was the first benzodiazepine that was produced primarily for use in anaesthesia.[1] Its effects on the central nervous system, respiratory system and cardiovascular system have been studied.[2] Although it is widely administered i.m. as premedication, little is known of its effect on thermoregulation. In a preliminary study, we found that premedication with i.m. midazolam decreased core temperature in surgical patients. We speculated that midazolam, in common with other anaesthetic adjuvants, impaired tonic thermoregulatory vasoconstriction, allowing core-to-peripheral heat redistribution.[3 4] Therefore, we tested the hypothesis that midazolam as i.m. premedication decreases core temperature dose-dependently.

## Subjects and methods

With the approval of the Committee on Human Research at the Yamanashi Medical University, we studied six male volunteers. None was obese, receiving medication or had a history of thyroid disease, dysautonomia or Raynaud's syndrome.

Volunteers were studied, in random order, on 3 days: (1) no midazolam administration (control day), (2) midazolam 0.025 mg $kg^{-1}$ i.m., (3) midazolam 0.075 mg $kg^{-1}$ i.m. All studies started at approximately 09:30. Volunteers fasted for 8 h before arriving at the laboratory. They were minimally clothed and covered with a single cotton blanket, and rested supine in a room at a temperature of 22–23 °C during the study.

On the first day subjects were maintained alert during a 30-min control period to avoid the effect of sleep on core and peripheral temperatures.[5] On the second and third days, midazolam 0.025 mg $kg^{-1}$ or 0.075 mg $kg^{-1}$ was administered i.m. Volunteers were kept in a quiet environment for 30-min after midazolam i.m.

Temperatures were monitored using Mon-a-Therm thermocouples (Mallinckrodt Anesthesiology Products, Inc., St Louis, MO, USA). The probes were connected to Mallinckrodt Model 6510

two-channel electronic thermometers. Core temperature was measured at the right tympanic membrane. The aural probe was inserted until volunteers felt the thermocouple touch the tympanic membrane; appropriate placement was confirmed when they easily detected a gentle rubbing of the attached wire. The probe was then taped securely in place and the aural canal occluded with cotton. Four adhesive skin surface probes were fixed on the chest, upper right arm, lateral calf and thigh. Mean skin temperature (MST) was calculated as $0.3\times(T_{\mathrm{chest}}+T_{\mathrm{arm}})+0.2\times(T_{\mathrm{thigh}}+T_{\mathrm{calf}})$.[6] Mean body temperature (MBT) was calculated as $0.34\times T_{\mathrm{MST}}+0.66\times T_{\mathrm{tym}}$.[7] Finger tip perfusion was evaluated using forearm minus fingertip and calf minus toe, skin surface temperature gradients. Perfusion was recorded from an arm and a leg which did not have an arterial pressure cuff or pulse oximeter.

Thirty minutes after administration of midazolam i.m., the level of sedation was assessed by a blinded observer according to the alertness/sedation scale.[8] The sedation scale is composed of four assessment categories: responsiveness, speech, facial expression and eyes. Each category is assessed. Responsiveness should be evaluated first. The composite score is assigned corresponding to the lowest levels at which any statement is checked. The composite score level ranges from 5 (alert) to 1 (deep sleep).

Peripheral venous blood was obtained immediately after measurement of sedation. Serum concentrations of midazolam were measured as follows: to the 0.25 ml of specimen was added 0.25 ml of sodium carbonate solution 1 mol $\mathrm{litre}^{-1}$, 50 μl of internal standard (prazepam) solution (1 μg $\mathrm{ml}^{-1}$ in $CHCl_3$ : benzene=10 : 9) and 3 ml of extracted solvent ($CHCl_3$ : benzene=10 : 9). The mixture was shaken for 10 min and centrifuged at 3000 rpm for 10 min. The 2 ml of separated organic layer was placed in a glass tube and evaporated to dryness under nitrogen at 35 °C. The residue was redissolved in 30 μl of toluene. A portion of this toluene solution was injected into the gas chromatograph (Hewlett Packard 5880A Series II, CA, USA).

Heart rate and oxyhaemoglobin saturation were measured continuously using pulse oximetry (Symphony N-3000, Nellcor Inc., CA, USA), and arterial pressure was determined oscillometrically at the left arm at the start and end of the study.

### DATA ANALYSIS

Haemodynamic responses, ambient temperature, oxyhaemoglobin saturation, and mean skin and mean body temperatures on each study condition were averaged between volunteers. Results for each study condition were compared using repeated-measures analysis of variance and Scheffé *F* tests. All results are presented as mean (SD) (range). $P<0.05$ was considered statistically significant.

## Results

Mean height of the volunteers was 169 (6) (160–177) cm, body weight 67 (11) (55–85) kg, age 30 (27–36) yr and basal surface area 1.8 (0.2) (1.6–2.1) $\mathrm{m}^2$. Ambient temperatures, mean arterial pressures, heart rates and oxyhaemoglobin saturation were comparable on the 3 study days. Mean skin temperatures on the midazolam 0.075 mg $\mathrm{kg}^{-1}$ day were significantly higher than those on the midazolam 0.025 mg $\mathrm{kg}^{-1}$ day. Mean body temperatures on the midazolam 0.025 and 0.075 mg $\mathrm{kg}^{-1}$ days were significantly lower than those on the control day (table 1).

Tympanic membrane temperatures on the midazolam 0.075 mg $\mathrm{kg}^{-1}$ i.m. day were significantly lower than those on the control and midazolam 0.025 mg $\mathrm{kg}^{-1}$ i.m. days at 20 and 30 min (fig. 1, table 2).

The decreases in tympanic membrane temperatures at 30 min after midazolam i.m. became larger

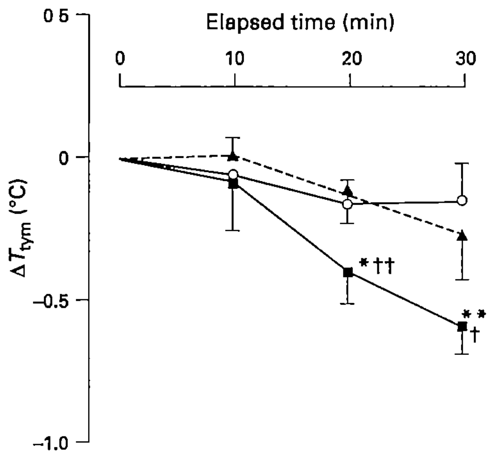

*Figure 1* Changes in tympanic membrane temperature ($\Delta T_{\mathrm{tym}}$) at 10, 20 and 30 min after administration of midazolam i.m. Tympanic membrane temperatures on the midazolam 0.075 mg $\mathrm{kg}^{-1}$ i.m. day (■) were significantly lower than those on the control (○) and midazolam 0.025 mg $\mathrm{kg}^{-1}$ i m. as the volunteers were more deeply sedated (fig. 2).

Figure 3 shows the regression for changes in tympanic membrane temperatures against blood concentrations of midazolam at 30 min after midazolam i.m. Midazolam linearly decreased core temperature.

The changes in skin surface temperature using forearm minus fingertip gradients (Δgradient (arm−finger)) and calf minus toe gradients (Δgradient (calf−toe)) at 30 min after midazolam i.m. on the midazolam 0.025 and 0.075 mg kg$^{-1}$ i.m. days were significantly larger than those on the control day (table 2).

## Discussion

Benzodiazepines have established themselves as useful drugs for premedication because of their sedative and anxiolytic effects, and good tolerance.[9] Midazolam is a benzodiazepine derivative with very rapid absorption, which is almost complete within 1 h, and peak concentrations are achieved in 30 min after i.m. administration.[10 11] Midazolam i.m. has been shown to be effective when used for preoperative sedation.[12] In this study, i.m. midazolam produced a concentration-dependent decrease in tympanic membrane temperature. This study was a simulation to test the effect of premedication with midazolam on core and peripheral temperatures in young volunteers.

Core temperature usually decreases by 0.5–1.5 °C during the first hour after induction of general anaesthesia.[13] In previous studies, even induction of general anaesthesia slightly increased cutaneous heat loss[14] and decreased metabolic heat production by 33%.[15] It is thus impossible to explain core hypothermia during the first hour of anaesthesia by this imbalance (metabolic heat production minus cutaneous heat loss). The decrease in heat production after administration of midazolam is less than that after induction of anaesthesia.[16] Accordingly, the imbalance between heat production and cutaneous heat loss contributed little to core hypothermia after i.m. administration of midazolam.

One possible mechanism for the decrease in core temperature is altered distribution of heat within the body. Heat is usually not distributed evenly within the body because tonic thermoregulatory vasoconstriction typically maintains a significant core-to-peripheral temperature gradient.[3 17] In this study, the Δgradients (arm−finger) and (calf−toe) showed a significant reduction (table 2) and indicated that core-to-peripheral heat redistribution occurred inside the body after administration of midazolam i.m. As the specific heat of most tissue is similar, heat content is greater in core than peripheral tissues. Although i.m. midazolam only slightly increases cutaneous heat loss, midazolam-induced vasodilatation allows redistribution of heat from the core thermal compartment to peripheral tissues. This process markedly decreases core temperature.

I.m. midazolam caused a linear decrease in core temperature in this study, proportional to its blood concentration. Clinically, for sedation as preoperative premedication, midazolam 0.07–0.10 mg kg$^{-1}$ i.m. is the dose range that has been studied and recommended.[2 12] We had observed in our preliminary study that all patients exhibited vasoconstriction before receiving midazolam i.m. as premedication. Therefore, the doses of midazolam usually used for premedication should decrease core temperature significantly. As midazolam and its active metabolite, α-hydroxy-midazolam, are eliminated with half-lives of approximately 3 h, our results are applicable to real clinical situations.[18]

# Effect of clonidine and dexmedetomidine premedication on perioperative oxygen consumption and haemodynamic state

M. T. TAITTONEN, O. A. KIRVELÄ, R. AANTAA AND J. H. KANTO

## Summary

Premedication has been shown to affect both oxygen consumption and metabolic rate. We have compared the perioperative metabolic and haemodynamic effects of two $\alpha_2$-agonists, clonidine and the more selective dexmedetomidine, in 30 ASA I patients undergoing plastic surgical procedures under general anaesthesia. Patients were premedicated with clonidine 4 $\mu g\ kg^{-1}$ ($n=10$), dexmedetomidine 2.5 $\mu g\ kg^{-1}$ ($n=10$) or saline ($n=10$) i.m. The doses of clonidine and dexmedetomidine were intended to be equipotent. The maximum decrease in preoperative oxygen consumption was 8% and decreases in systolic and diastolic arterial pressures were 11% from baseline after clonidine and dexmedetomidine. During operation, the maximum reduction in heart rate was 18% in the clonidine and dexmedetomidine groups compared with the placebo group. After operation, the maximum decrease in systolic arterial pressure was 11%, diastolic arterial pressure 15% and oxygen consumption 17% in the clonidine and dexmedetomidine groups compared with placebo. In summary, both clonidine 4 $\mu g\ kg^{-1}$ and dexmedetomidine 2.5 $\mu g\ kg^{-1}$ decreased perioperative oxygen consumption effectively, with a similar haemodynamic profile. (*Br. J. Anaesth.* 1997; **78**: 400–406).

**Key words**
Sympathetic nervous system, clonidine. Sympathetic nervous system, dexmedetomidine. Cardiovascular system, effects. Oxygen, consumption.

$\alpha_2$-Agonists are currently used as sedatives and anaesthetics in veterinary anaesthesia and clonidine is also used as an adjunct to anaesthesia and as an extradural–intrathecal analgesic in humans.[1] Both clonidine and dexmedetomidine, a more selective and specific $\alpha_2$-agonist, have been shown to decrease induction doses of i.v. anaesthetics and to decrease intraoperative opioid and volatile anaesthetic requirements for maintenance of anaesthesia.[1] In addition, they have been shown to decrease perioperative catecholamine concentrations[1 2] and promote perioperative haemodynamic and adrenergic stability.[1]

Perioperative stress associated with surgery and anaesthesia evokes an endocrine response that includes stimulation of the sympathetic nervous system.[3] This increases circulating plasma adrenaline and noradrenaline concentrations with consequent increases in arterial pressure, heart rate and oxygen consumption.[3 4] Controlling this perioperative stress response is an important goal of modern anaesthesia.[5]

We have compared the perioperative metabolic and haemodynamic effects of clonidine and dexmedetomidine to determine if the more selective agonist, dexmedetomidine, has any clinical advantages over clonidine.

## Patients and methods

The study was double-blind, randomized and placebo-controlled, and was approved by the Ethics Committee of Turku University Hospital. After obtaining written informed consent, we studied 30 ASA I patients undergoing elective plastic surgical procedures under general anaesthesia (table 1). Patients with known drug hypersensitivity were excluded.

Patients entered the hospital 1 day before the scheduled surgery and were interviewed and examined. Routine laboratory testing was performed. No hypnotic medication was given on the evening before surgery.

After fasting overnight, patients were transferred to the recovery room where pre- and postoperative assessments were performed. Patients were resting supine in their hospital beds and were allowed to listen to music of their choice. Measurements were started at 08:00–09:00.

On arrival in the study area, ungraded visual analogue scales (VAS) were introduced and preoperative baseline anxiety, tiredness and dryness of the mouth were assessed. If the patient was asleep during the later course of the session and could not be awakened by voice command a score of zero was recorded for anxiety and a score of 100 was recorded for tiredness. In such case dryness of mouth was not recorded.

Before the metabolic measurements, continuous monitoring of the electrocardiogram and heart rate (HR), together with non-invasive recording of systolic (SAP), mean (MAP) and diastolic (DAP) arterial pressures (Cardiocap II, Datex/Instrumentarium, Helsinki, Finland) was commenced. Arterial haemoglobin oxygen saturation ($Sp_{O_2}$) was measured using pulse oximetry (Cardiocap II, Datex/Instrumentarium, Helsinki, Finland). The recordings were made at 5-min intervals (before, during and after operation).

After assessment of baseline tiredness, anxiety and dryness of mouth and a 15-min stabilization period under the metabolic monitor canopy (see below), metabolic measurements, energy expenditure (EE), oxygen consumption ($\dot{V}O_2$) and carbon dioxide production ($\dot{V}CO_2$) were started. The first consecutive 15 min after stabilization were used for determining baseline metabolic and haemodynamic values. After these baseline measurements patients were premedicated.

Patients were allocated randomly to receive clonidine 4 $\mu$g kg$^{-1}$ (Catapresan, Boehringer Ingelheim, Ingelheim am Rhein, Germany), dexmedetomidine 2.5 $\mu$g kg$^{-1}$ (provided by Orion Corporation, Orion-Farmos, Turku, Finland) or placebo (3 ml of 0.9% NaCl) in a double-blind manner. Drugs were administered into the deltoid muscle 40–50 min before anticipated induction of anaesthesia. The doses of clonidine and dexmedetomidine were selected to provide comparable preoperative effects.[6 7]

The double-blind nature of the study was ensured by having an independent nurse, not participating in the study, prepare clonidine or dexmedetomidine in ready-to-inject forms by dilution in 3 ml with physiological saline.

After premedication, metabolic and haemodynamic values were recorded for 30 min. Metabolic measurements (before and after operation) were made at 1-min intervals and the recorded values were means of 15 consecutive measurements. VAS scores for tiredness, anxiety and dryness of mouth were recorded 30 min after premedication, that is at the end of the preoperative study session. Patients were then transferred to the operating room and anaesthesia was induced 10–20 min after completion of the preoperative follow-up period.

During operation, SAP, MAP, DAP, $Sp_{O_2}$ and HR were recorded for 45 min. The first value was recorded 5 min before induction of anaesthesia and the second value 5 min after tracheal intubation. Recording of EE, $\dot{V}O_2$ and $\dot{V}CO_2$ was started 15–30 min after intubation, when equilibrium of end-tidal carbon dioxide (4.5–5%) had been achieved with controlled ventilation. The ventilator settings (tidal volume, breath rate, $FI_{O_2}$) were not altered thereafter. Metabolic measurements were performed during surgery at 1-min intervals and the recorded values were means of five consecutive measurements. Metabolic values were recorded for 30 min because of differences in duration of anaesthesia and surgery and thus incomplete data thereafter.

After operation SAP, MAP, DAP, HR, $Sp_{O_2}$, EE, $\dot{V}O_2$ and $\dot{V}CO_2$ values were recorded for 90 min. Metabolic monitoring was started as soon as the patient required no ventilatory assistance or supplementary oxygen to comply with $Sp_{O_2}$ >90% after tracheal extubation. VAS scores for tiredness, anxiety and dryness of mouth were recorded at the end of the 90 min postoperative measurement period. Postoperative shivering (yes/no) and analgetic requirements were recorded.

### METABOLIC MEASUREMENTS

Metabolic measurements were performed using a portable metabolic cart system (Deltatrac, Datex/Instrumentarium, Helsinki, Finland). The Deltatrac is an open system, indirect calorimetry device designed to measure $\dot{V}O_2$ and $\dot{V}CO_2$ in both spontaneously breathing patients and those undergoing mechanical ventilation.[8] Deltatrac has been shown to have good overall accuracy (in a respirator model: mean error 2±2 % for $\dot{V}CO_2$ and 4±4 % for $\dot{V}O_2$[8]; in a canopy model: mean error 3±2 % for $\dot{V}CO_2$ and 4±2 % for $\dot{V}O_2$[8]). Flow calibration was performed by alcohol burning before the study. The monitor was calibrated further using a standard gas mixture containing 95% oxygen and 5% carbon dioxide, before each session.

For measurements in spontaneously breathing patients the subject's head was placed under a plastic cone (canopy) connected to the analyser. The canopy was half-ellipsoidal and made of 1-mm thick transparent PVC plastic. It has adapters for tubing and with a wide edge of soft plastic cloth to make construction airtight around the head and neck of the subject. Minor leakages do not affect the results as they are directed inwards because of the slight underpressure inside the canopy caused by the constant airflow (40 litre min$^{-1}$) drawn through the canopy to the gas analysers, and thus all expired gases are captured. The difference between inspired (sampling at the entry valve of the canopy) and expired oxygen fractions ($FI_{O_2}$, $FE'_{O_2}$) is measured with a fast-response paramagnetic differential oxygen sensor (OM-101, Datex/Instrumentarium, Helsinki, Finland). The expired carbon dioxide fraction ($FE'_{CO_2}$) is measured with an infrared carbon dioxide sensor. A microcomputer controls a set of magnetic valves for automatic control of absolute $FI_{O_2}$, the inspired carbon dioxide fraction ($FI_{CO_2}$) and gas analyser baselines. During mechanical ventilation the device is connected to the outlet port of the ventilator and expired air is collected through a built-in mixing chamber. The mixed expiratory gases are then diluted in the mainstream of the constant flow generator. $FI_{O_2}$ and $FI_{CO_2}$ are measured from the inspiratory limb of the ventilator, and $FE'_{O_2}$ and $FE'_{CO_2}$ from the mixing chamber. The fraction of carbon dioxide in the diluted expiratory gases, downstream from the flow generator, is also measured.

$\dot{V}CO_2$ was calculated in both canopy and ventilator measurements as the product of constant flow and fraction of carbon dioxide in diluted expiratory flow: $\dot{V}CO_2 = Q \times FE'_{CO_2}$, where $Q$=constant flow.

With the canopy, $\dot{V}O_2$ is calculated using the Haldane transformation[9]:

$$\dot{V}O_2=(Q/(1-F\mathrm{I}_{O_2}))\times(F\mathrm{I}_{O_2}-F\mathrm{E}'_{O_2}-F\mathrm{I}_{O_2}\times(F\mathrm{E}'_{CO_2}-F\mathrm{I}_{CO_2}))$$

where $F\mathrm{E}'_{O_2}$ and $F\mathrm{E}'_{CO_2}$=fractions of oxygen and carbon dioxide in mixed expiratory gas flowing through the monitor.

During ventilator measurement, RQ was calculated using the Haldane transformation from the gas fractions[9]: $RQ=1-F\mathrm{I}_{O_2}/(F\mathrm{I}_{O_2}-F\mathrm{E}'_{O_2})/F\mathrm{E}'_{CO_2}-F\mathrm{I}_{O_2}$, where $F\mathrm{E}'_{O_2}$ and $F\mathrm{E}'_{CO_2}$ were measured from the mixing chamber. The expiratory gases from the respirator flow through the mixing chamber and then form a constant flow and concentration through the system. $\dot{V}CO_2$ was calculated as the product of constant flow and concentration of carbon dioxide downstream from the mixing chamber identical to the canopy measurement. $\dot{V}O_2$ was subsequently calculated from RQ as: $\dot{V}O_2=\dot{V}CO_2/RQ$.

Energy expenditure (EE) was calculated from the measured rates of $\dot{V}O_2$ and $\dot{V}CO_2$: $EE=3.581\times\dot{V}O_2+1.448\times\dot{V}CO_2-32.4$, where EE is given in kcal day$^{-1}$, $\dot{V}O_2$ in litre day$^{-1}$, and $\dot{V}CO_2$ in litre day$^{-1}$.[8 10]

All calculations were performed at 1-min intervals, and the results were stored for further processing.

### ANAESTHETIC MANAGEMENT

On arrival in the operating theatre, peripheral i.v. infusion of lactated Ringer's solution was started. No glucose was infused during the study. Immediately before induction of anaesthesia, patients received fentanyl (Fentanyl, Orion Corporation, Medipolar, Oulu, Finland) 2 μg kg$^{-1}$ i.v. While patients breathed 100% oxygen via a face mask, anaesthesia was induced with propofol 2–2.5 mg kg$^{-1}$. Atracurium 0.5 mg kg$^{-1}$ was given i.v. to facilitate laryngoscopy and tracheal intubation. For further neuromuscular block, atracurium was administered to maintain 95% block, as assessed by a neurostimulator (Innervator NS 252, Fisher and Paykel Electronics Ltd, Healthcare Division, Auckland, NZ). Anaesthesia was maintained with infusion of propofol 6–8 mg kg$^{-1}$ h$^{-1}$. Patients also received fentanyl bolus doses of 1 μg kg$^{-1}$ at 30-min intervals. Signs of inadequate anaesthesia (i.e. HR or SAP >20% of pre-induction values, lacrimation, sweating and flushing) were treated by increasing the rate of infusion of propofol and by administering an i.v. bolus of fentanyl 1 μg kg$^{-1}$. Controlled ventilation (Servo 900D, Siemens-Elema, Solana, Sweden) with 30% oxygen in air was adjusted before the metabolic measurements to maintain an end-tidal carbon dioxide concentration (Cardiocap II, Datex/Instrumentarium, Helsinki, Finland) of 4.5–5%. End-tidal carbon dioxide was not measured during metabolic measurements to avoid leaks from the closed gas system. Inspiratory oxygen was stabilized using an extra humidifier in the ventilator inspiratory limb. Oesophageal temperature measurement was started immediately after tracheal intubation. Temperature of the patient was kept at more than 36 °C by warming the fluids and operating tables and by using warmed cotton blankets placed over the patient during and after operation.

Hypotension was treated primarily by decreasing the infusion rate of propofol. Bradycardia, defined as HR <40 beat min$^{-1}$, was treated with a bolus dose of atropine 1 mg i.v. At the end of surgery patients were allowed to recover spontaneously from neuromuscular block. The trachea was extubated when sufficient spontaneous ventilation was evident.

### STATISTICAL ANALYSIS

For repetitive data (SAP, MAP, DAP, HR, $Sp_{O_2}$, $\dot{V}O_2$, $\dot{V}CO_2$), differences between groups were analysed using two-way repeated measures analysis of covariance (ANCOVA), with time as the within-factor and drug as the between-factor. When a statistically significant drug effect or drug×time interaction was present, the analysis was continued by applying contrasts for each group.[11] The comparability of the groups with respect to patient and operational characteristics was analysed using one-way analysis of variance (ANOVA) or chi-square test (sex, number of patients requiring supplementary oxygen). VAS scores were analysed using ANOVA.[12] $P<0.05$ was considered significant.

## Results

The groups were similar in patient and operational characteristics (table 1). None of the patients needed blood products or colloids.

Dryness of mouth and tiredness increased towards the end of the preoperative follow-up period

*Table 1* Patient and operational characteristics (mean (SD or range) or number). BMR=Baseline metabolic rate, measured by indirect calorimetry; Anaesthesia=duration of anaesthesia; Surgery=duration of surgery. Propofol, fentanyl and atracurium doses are total doses. *Figure 1* Perioperative heart rate (HR), systolic (SAP) and diastolic (DAP) arterial pressure (mean, SD) in the placebo (●), clonidine (■) and dexmedetomidine (▲) groups. Before operation (Preop.) drug administration was at time 0; during operation (Intraop.) time 0=5 min before induction of anaesthesia and time 10=10 min after tracheal intubation. D=$P$ value for drug effect; T=$P$ value for time effect; DxT=$P$ value for drug×time interaction in overall ANCOVA.

($P$≤0.001 for time factor) in all three groups, with dexmedetomidine causing more dryness of mouth than placebo ($P$=0.018 in pairwise comparisons) (table 2). There were no significant differences in tiredness between groups (table 2).

Before operation, SAP and MAP decreased after clonidine ($P$=0.0044 and $P$=0.0090, respectively, in pairwise comparisons) and dexmedetomidine ($P$=0.014 and $P$=0.016, respectively, in pairwise comparisons) compared with placebo. Clonidine also decreased DAP compared with placebo ($P$=0.048 in pairwise comparisons). The mean maximum decrease in SAP and DAP after clonidine was 11% from baseline values (fig. 1).

Pre-induction values of SAP, MAP and DAP, measured 5 min before induction of anaesthesia, were lower in the clonidine and dexmedetomidine groups ($P$<0.05 in pairwise comparisons) and HR was lower in the dexmedetomidine group than in the placebo group ($P$=0.025 in pairwise comparisons). One female patient with a HR of 38 beat min$^{-1}$ before laryngoscopy in the dexmedetomidine group had a sinus pause during intubation. The sinus pause lasted for approximately 3 s and was treated with atropine 1 mg i.v. This patient was excluded from the study. No other patient needed atropine or any other vasoactive agent during the study.

During operation, HR was lower (approximately 18%) in the clonidine and dexmedetomidine groups compared with the placebo group ($P$=0.0047 and

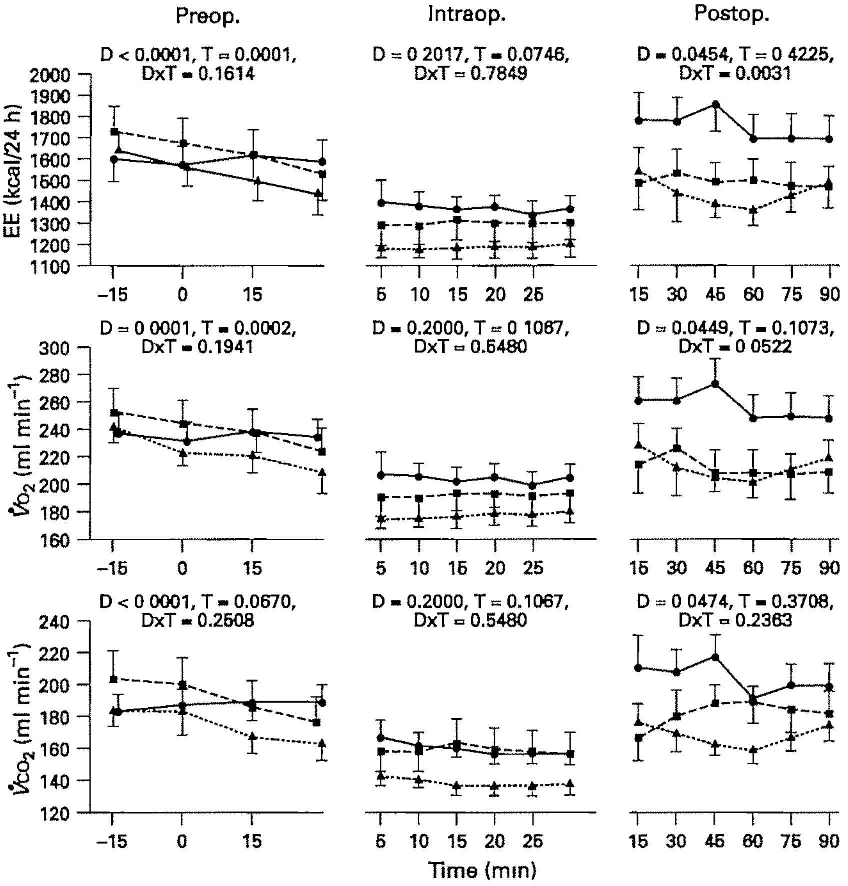

*Figure 2* Perioperative oxygen consumption ($\dot{V}O_2$), carbon dioxide production ($\dot{V}CO_2$) and energy expenditure (EE) (mean, SD) in the placebo (●), clonidine (■) and dexmedetomidine (▲) groups. Before operation (Preop.) drug administration was at time 0. During intraoperative (Intraop.) metabolic measurements, surgery was proceeding. D=*P* value for drug effect; T=*P* value for time effect; DxT=*P* value for drug×time interaction in overall ANCOVA.

$P$=0.0032, respectively, in pairwise comparisons) (fig. 1).

After operation, SAP was lower in the dexmedetomidine group ($P$=0.045 in pairwise comparisons) and HR was lower in the clonidine group compared with the placebo group ($P$=0.024 in pairwise comparisons). DAP and MAP were lower after both clonidine ($P$=0.010 and $P$=0.014, respectively, in pairwise comparisons) and dexmedetomidine ($P$=0.0213 and $P$=0.024, respectively, in pairwise comparisons) compared with placebo. SAP was approximately 11% lower and DAP approximately 15% lower in the clonidine and dexmedetomidine groups than in the placebo group (fig. 1).

There were no significant differences in pre- and intraoperative $Sp_{O_2}$ values. After operation, after complete recovery from neuromuscular block, eight patients in the dexmedetomidine group, five in the clonidine and four in the placebo group had clinically inadequate ventilation and required supplementary oxygen during the emergence period immediately after tracheal extubation. There were no differences in the numbers of patients requiring supplementary oxygen ($P$=0.155) or duration ($P$=0.644) of administration of supplementary oxygen between groups.

Before operation, clonidine and dexmedetomidine caused a greater decrease in $\dot{V}O_2$, $\dot{V}CO_2$ and EE than placebo ($P$<0.001 for all variables in pairwise comparisons). There were no differences in RQ between the groups. The maximum decrease in $\dot{V}O_2$, $\dot{V}CO_2$ and EE was 8% from baseline in the clonidine group and 7% from baseline in the dexmedetomidine group (fig. 2).

During operation, there were no differences in the metabolic variables between groups, although $\dot{V}O_2$ and EE tended to be lower in the clonidine and dexmedetomidine groups than in the placebo group (fig. 2).

After operation, $\dot{V}O_2$ was lower (approximately 17%) in the clonidine and dexmedetomidine groups than in the placebo group ($P$=0.049 and $P$=0.021, respectively, in pairwise comparisons) (fig. 2). $\dot{V}CO_2$ and EE were lower after dexmedetomidine (approximately 17% and 19%, respectively) compared with placebo ($P$=0.014 for both variables in pairwise comparisons) (fig. 2).

Patients in the clonidine and dexmedetomidine groups tended to be more sedated than patients in the placebo group, although there were no significant differences between the groups in tiredness after operation ($P$=0.269) (table 2). There were no differences between the groups in postoperative analgesic requirements. One patient in the dexmedetomidine group received metoclopramide for nausea and vomiting. Two patients in the placebo group and none in the clonidine or dexmedetomidine groups experienced shivering after operation.

## Discussion

The $\alpha_2$-agonists, including clonidine and dexmedetomidine, decrease central sympathetic outflow and modify intraoperative cardiovascular and endocrine responses favourably to surgical stimuli and laryngoscopy.[1 2] The reduction in tachycardia, hypertension, sympathetic activity and consequently total body oxygen consumption may be of benefit in patients at risk of developing inadequate cardiac output or myocardial ischaemia.[4 5 13]

In this study both clonidine 4 μg $kg^{-1}$ and dexmedetomidine 2.5 μg $kg^{-1}$ had metabolic effects of similar magnitude. Before operation, the maximum decrease in $\dot{V}O_2$ and EE was 7–8 %. The *t*max value of i.m. clonidine is 54 min[14] and that of dexmedetomidine 1.6 h.[15] Thus a greater decrease may occur during a longer observation period as we recorded $\dot{V}O_2$ and EE for only 30 min. I.v. dexmedetomidine 1–2 μg $kg^{-1}$ has been shown previously to decrease $\dot{V}O_2$ in healthy volunteers.[16] In that study $\dot{V}O_2$ showed a biphasic response, as there was an initial increase in $\dot{V}O_2$, 10 min after drug administration, followed by a sharp decrease below the baseline value, 60 min after drug administration (maximum of 17% on average from baseline). In our study we did not notice an increase in $\dot{V}O_2$. This may be because of slower absorption after i.m. administration and lack of high peak concentrations and consequent haemodynamic effects after an i.v. bolus of clonidine and dexmedetomidine.[1] During operation, $\dot{V}O_2$ and EE tended to be lower in the clonidine and dexmedetomidine groups (fig. 2). However, these differences were not statistically significant because $\dot{V}O_2$ and EE were well controlled by the anaesthetics in all groups. After operation, the decrease in $\dot{V}O_2$ (approximately 17%) observed in this study after clonidine and dexmedetomidine was of similar magnitude to that reported previously after an i.v. bolus of clonidine 2 mg $kg^{-1}$.[17]

Both clonidine and dexmedetomidine have been shown to reduce sympathetic nervous system activity and plasma catecholamine concentrations.[1 2] This results in decreased whole body metabolism while the decrease in cardiac output related to clonidine and dexmedetomidine[13 18] may lead to decreased myocardial oxygen consumption.[18] These combined effects may contribute to the reduction observed in $\dot{V}O_2$ and EE after clonidine and dexmedetomidine. Similarly, the analgesic effects of clonidine and dexmedetomidine[1 14] and the indirect effects of sedation and neuromuscular block[1] might account in part for the reduction in $\dot{V}O_2$. It has been demonstrated that effective analgesia in the postoperative period can decrease $\dot{V}O_2$ by up to 7–8 %.[19]

Recovery from general anaesthesia is associated with shivering and an increase in $\dot{V}O_2$.[20] In our study only two patients in the placebo group had moderate shivering. Although clonidine has been shown to reduce post-anaesthetic shivering,[17] the low incidence of shivering in our study could be explained partly by the anaesthetic conditions: both propofol[21] and fentanyl[22] have been shown to reduce shivering. Patients were also warmed during and after operation to avoid hypothermia.

The metabolic measurements were performed using an open circuit indirect calorimeter. When used in patients undergoing mechanical ventilation these calorimeters are very sensitive to fluctuations in $FI_{O_2}$ and generally invalid with $FI_{O_2}$ values greater than 0.8. This is because of their reliance on the Haldane transformation (HT) to determine $\dot{V}O_2$, which includes an assumption that no other gases apart from oxygen, carbon dioxide and nitrogen are present in the system. Other gases, such as volatile anaesthetics and nitrous oxide, invalidate the equation.[23] To avoid the confounding effects of these gases on HT, we induced and maintained anaesthesia with i.v. propofol and fentanyl and ventilated the lungs of patients with 30% oxygen in air. As open circuit calorimeters are also affected by leaks, analysis of end-tidal carbon dioxide was arrested during the measurement periods. Canopy measurements are not affected by minor leakages as they are directed inward because of the slight underpressure inside the canopy.

The decrease in arterial pressure (AP) and HR after both clonidine and dexmedetomidine premedication was of a similar magnitude (fig. 1). These hypotensive and bradycardic effects of $\alpha_2$-agonists are presumably mediated by activation of $\alpha_2$-adrenoceptors or imidazoline-preferring receptors, or both, in the ventrolateral medulla, especially in the nucleus tractus solitarius.[1 24] In our study AP and HR tended to increase in the dexmedetomidine group but not in the clonidine group at the end of the postoperative follow-up period (fig. 1). This is in line with the pharmacokinetic variables of these compounds. The terminal half-life of a single i.m. bolus of dexmedetomidine is approximately 4 h[7]; that of an i.v. bolus of clonidine is approximately 8.5 h.[25] Hypotension and bradycardia are also major adverse effects of $\alpha_2$-agonists. In our study, one female patient in the dexmedetomidine group had a sinus pause of short duration during intubation with a HR of 38 beat $min^{-1}$ before laryngoscopy. This raises concern regarding the use of $\alpha_2$-agonists in patients with high parasympathetic tone.[1]

$\alpha_2$-Agonists reduce perioperative anaesthetic and analgesic requirements.[1] However, there were no significant differences in opioid or i.v. anaesthetic requirements between the groups in our study, probably because the induction and maintenance doses of fentanyl and propofol were intended to be equipotent in all three groups. This was to avoid the effect of different doses of propofol and fentanyl on postoperative energy metabolism and haemodynamic state.

Although previously reported to be anxiolytic,[1] neither clonidine nor dexmedetomidine provided anxiolysis in our investigation. Baseline anxiety values observed in this study were only moderate in all three groups (table 2). Moreover, most of the surgical procedures were minor and patients showed little apprehension in the ward, making demonstration of anxiolysis difficult.

# Regional cerebral blood flow (SPECT) during anaesthesia with isoflurane and nitrous oxide in humans

P. REINSTRUP, E. RYDING, L. ALGOTSSON, L. BERNTMAN AND T. USKI

## Summary

Nitrous oxide and isoflurane have different effects on absolute cerebral blood flow (CBF) and regional distribution of CBF in humans. In this study we examined the effects of isoflurane in combination with nitrous oxide on CBF. We studied 10 patients (two groups of five patients, ASA I) anaesthetized with 50% nitrous oxide and either 0.5 or 1.0 MAC of isoflurane during normocapnia ($Pa_{CO_2}$ 5.7 kPa) using two-dimensional CBF measurement ($CBF_{xenon}$) (i.v. $^{133}$xenon washout technique) and a three-dimensional method for measurement of regional CBF (rCBF) distribution with SPECT (single photon emission computer-aided tomografy with $^{99m}$Tc-HMPAO). The results were compared with 1.0 MAC of isoflurane from a previous study performed in exactly the same way as the present investigation. During normocapnia, anaesthesia with 50% nitrous oxide and 0.5 MAC of isoflurane resulted in a mean $CBF_{xenon}$ of 45 (SEM 5) ISI units. Increasing the isoflurane concentration to 1.0 MAC had no significant effect on mean $CBF_{xenon}$ (53 (5) ISI units). Both flow values were significantly ($P$=0.01) higher than the $CBF_{xenon}$ value obtained when 1 MAC of isoflurane was administered alone (33 (3) ISI units). There were no significant differences in rCBF distribution regardless of whether or not isoflurane was given alone or together with nitrous oxide at 0.5 or 1 MAC. In all situations there were higher relative flows in subcortical regions (thalamus and basal ganglia, 10%) and in the pons (7–10% above average). rCBF in the cerebellum was approximately 10% greater than average. In summary, we have found that mean CBF was greater with combined nitrous oxide and isoflurane anaesthesia than previously found with isoflurane alone; however, relative flow distribution was similar. (*Br. J. Anaesth.* 1997; **78**: 407–411).

**Key words**
Anaesthetics volatile, isoflurane. Anaesthetics gases, nitrous oxide. Brain, blood flow. Measurement techniques, tomography.

Nitrous oxide has been used for anaesthesia during neurosurgical procedures for half a century as it was thought to have only little effect on the cerebral circulation.[1 2] However, by the 1970s it was shown that nitrous oxide had marked effects on intracranial pressure (ICP)[3 4] but the literature on the effects of nitrous oxide on the brain is confusing, probably because of species differences, but also because of interactions with other drugs or interventions.[5 6] However, in humans, evidence supporting the conclusion that nitrous oxide is a cerebral vasodilator, in the absence of other interventions, has been obtained previously from cerebral blood flow (CBF) studies.[7–9] Recent studies have shown that nitrous oxide increases blood flow velocity also when it is added to propofol or isoflurane anaesthesia.[10 11] The reason for this vasodilatation is still unknown, but it may theoretically be caused by increased cerebral metabolism[10–13] or by an indirect effect on the cerebral vessels[9 14] as it is known that nitrous oxide is totally inert on isolated human pial arteries.[9]

The aim of this study was to evaluate the effect of isoflurane in combination with 50% nitrous oxide on absolute CBF measured by i.v. $^{133}$xenon[15] combined with recording of the three-dimensional rCBF distribution with SPECT and $^{99m}$Tc-HMPAO in normocapnic patients.

## Patients and methods

We studied 10 male patients, ASA I, undergoing inguinal herniorrhaphy. The study was approved by the Ethics Committee of the Medical Faculty and the Isotope Committee of the University of Lund. Written informed consent was obtained from each participant.

### EXPERIMENTAL PROCEDURE

Ten patients were allocated randomly to one of two groups ($n$=5 in each group), to receive 50% nitrous oxide and 0.5 or 1 MAC of isoflurane during normocapnia. The group who received isoflurane alone also comprised five patients who have been reported

Correspondence to P. R.

previously.[16] Subjects in the previous study were anaesthetized with 1 MAC of isoflurane alone, but otherwise treated in the same way as patients in the present investigation.

No premedication was given. Anaesthesia was induced with pethidine 0.75 mg $kg^{-1}$ i.v. and propofol 2–2.5 mg $kg^{-1}$. Suxamethonium 1 mg $kg^{-1}$ was used to facilitate tracheal intubation. Mechanical ventilation was with a Servo ventilator (Siemens 900 C, Siemens Elema, Solna, Sweden). End-tidal carbon dioxide and concentrations of isoflurane were recorded on a Normocap 102-24-02 and a Normac gas monitor (Datex, Helsinki, Finland), respectively. Anaesthesia was maintained with isoflurane and 50% nitrous oxide in oxygen. End-tidal concentrations of isoflurane and carbon dioxide ($PE'_{CO_2}$) were maintained as close as possible to the final experimental condition throughout anaesthesia.

At 10–20 min before the end of surgery, patients were kept anaesthetized with either 0.5 or 1 MAC of isoflurane and 50% nitrous oxide in oxygen for at least 30 min. When stable conditions were achieved and surgery had finished, mean CBF was measured using i.v. radioactive $^{133}$xenon clearance ($CBF_{xenon}$). $^{99m}$Tc-HMPAO was given immediately after the $CBF_{xenon}$ measurement and anaesthesia was maintained for 5 min more. No patient was studied sooner than 60 min after induction of anaesthesia (mean 69 min, range 60–85 min). After a post-anaesthetic recovery period of 1–2 h, patients were brought to the neurophysiological department for SPECT scanning.

During measurement of mean $CBF_{xenon}$, haemoglobin concentration and arterial blood-gas samples were analysed using an ABL 500 (Radiometer, Copenhagen, Denmark). Temperature, heart rate and systemic arterial pressure were monitored throughout the procedure.

### MEASUREMENT OF MEAN CEREBRAL BLOOD FLOW

Mean $CBF_{xenon}$ was measured by injection of 0.5 Gbq (10 mCi) of $^{133}$xenon into a cubital vein, followed by rapid injection of 20 ml of isotonic saline. Uptake and clearance of the tracer substance were recorded with a scintillation detector with wide collimation (approximately 90° view), placed on the right side of the head over the parieto-temporal region, including most of the brain in its field. Clearance through the lungs was recorded from expired air. A Novo Cerebrograph 10a (Simonsen Medical A/S, Randers, Denmark) was used for data collection with a sampling time of 11 min and subsequent flow calculation. $CBF_{xenon}$ was expressed as the initial slope index (ISI)[17] as it represents blood flow of all tissue recorded, but is highly dominated by gray matter blood flow and influenced little by extracerebral components.[17]

### MEASUREMENT OF THREE-DIMENSIONAL CEREBRAL BLOOD FLOW DISTRIBUTION

Regional distribution of CBF was measured by injection of a tracer substance, $^{99m}$Tc- HMPAO 0.5 Gbq (10 mCi) (Ceretec, Amersham, UK) into a cubital vein, followed by rapid injection of 20 ml of isotonic saline. This tracer substance is lipid soluble at the time of injection and is distributed in proportion to blood flow. In brain cells the carrier molecule HMPAO is converted within a few minutes to a water-soluble form which cannot cross the cell membrane. Hence, the amount of $^{99m}$Tc (half-life of 6 h) which remains trapped in the brain cells is proportional to rCBF distribution. Cerebral $^{99m}$Tc distribution was recorded three-dimensionally with a single photon emission computer-aided tomography (SPECT) scanner (Tomomatic 564, Medimatic A/S, Denmark) giving a picture of rCBF distribution at the time of $^{99m}$Tc-HMPAO injection.[18 19] Three-dimensional distribution of $^{99m}$Tc-HMPAO in the brain was recorded in 10 contiguous, approximately 1-cm thick, slices parallel to the orbitomeatal (OM) line, with the centre of the lowest slice located 1 cm below the OM line. The head position was controlled with light beams on the external auditory meatus and the nasion. Slices were recorded in two interlacing sets of five slices each with a recording time of 10 min for each set, which gave approximately $10^6$ counts/slice and an intra-slice resolution of approximately 1 cm. The regions of interest were positioned automatically within each slice, with adjustment to the subject's brain size.

### CALCULATIONS AND STATISTICAL METHODS

The mean $CBF_{xenon}$ value recorded from our detector corresponded to a weighted average of different brain regions, with the weight of each region in the average determined mainly by its $^{133}$xenon content and distance from the detector.[20] Consequently, the $CBF_{xenon}$ value from the parietal detector was an average between CBF in the closest cortical tissue (parietal cortex) and mean CBF, with dominance for the parietal cortex.

In the SPECT $^{99m}$Tc-HMPAO measurements, the average CBF level, calculated as the average number of counts through all regions, gray and white matters, was defined as 100% for presentation of relative flow values. Regions of interest were outlined in the brain slices by a program which was constructed from anatomical templates in a CT brain atlas.[21] Three- dimensional cerebral regions of interest were calculated from adjoining regions of interest in different brain slices representing the same structure. The program gave the mean value in each region of interest and the size of the region of interest.

With the SPECT $^{99m}$Tc-HMPAO measurements, parietal and average CBF had virtually the same value (>>100%) and therefore it was justifiable to approximate the recorded $CBF_{xenon}$ value to parietal cortical CBF. Regional CBF values were calculated from $CBF_{xenon}$ mean flow values and $^{99m}$Tc-HMPAO rCBF distribution, as described by Reinstrup and colleagues.[16] Thus $CBF_{xenon}$ values were equated with parietal values in the regional distribution obtained with SPECT.

The conversion factor from kPa to mm Hg was 0.1333.

All values are given as mean (SEM). Mean

$CBF_{xenon}$ values were tested by factorial design ANOVA, initially on global anaesthesia effects and *post hoc* on the addition of nitrous oxide to isoflurane anaesthesia. Regional CBF ($^{99m}$Tc-HMPAO distribution) was analysed by repeated measures ANOVA with anaesthetic type as between-group factor and regions of interest as within-group factors. $P<0.05$ was considered statistically significant.

## Results

Physiological values of the three groups, at the time of mean CBF measurement, are presented in table 1.

### EFFECTS OF NITROUS OXIDE AND ISOFLURANE ON MEAN $CBF_{XENON}$ USING $^{133}$XENON

There was a significant ($F=5.36$, $P=0.022$ ANOVA) effect on $CBF_{xenon}$ of anaesthesia type. Patients without any surgical stress anaesthetized with 50% nitrous oxide and 0.5 MAC of isoflurane (0.6%) had a mean $CBF_{xenon}$ of 45 (5) ISI units during normocapnia. $CBF_{xenon}$ during isoflurane anaesthesia at 1 MAC (1.2%) and during 50% nitrous oxide did not differ significantly from the flow value with 0.5 MAC (53 (5) ISI units). Compared with 1 MAC of isoflurane alone (CBF=33 (3) ISI units)[16] both $CBF_{xenon}$ values with nitrous oxide in addition to isoflurane were significantly increased ($F=8.16$, $P=0.014$).

*Table 1* Physiological values for the three groups ($n=5$ in each group). Values are mean (SEM or range)

| | $N_2O$+0.5 MAC of isoflurane | $N_2O$+1.0 MAC of isoflurane | 1.0 MAC of isoflurane |
|---|---|---|---|
| Age (yr) | 30 (21–45) | 33 (20–44) | 43 (37–50) |
| $Pa_{CO_2}$ (kPa) | 5.7 (0.1) | 5.8 (0.3) | 5.4 (0.1) |
| $Pa_{O_2}$ (kPa) | 35 (2) | 30 (2) | 32 (8) |
| pH | 7.39 (0.01) | 7.38 (0.02) | 7.41 (0.02) |

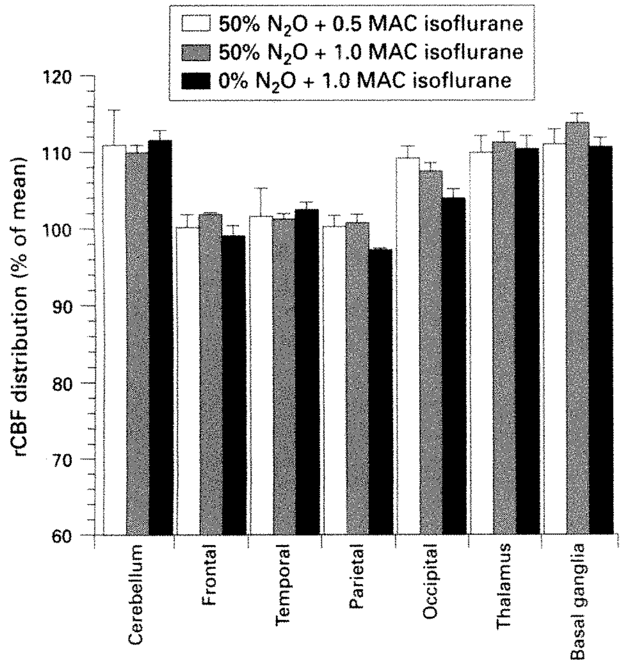

*Figure 1* Regional cerebral blood flow (rCBF) distribution (% of mean relative CBF) during anaesthesia with 50% nitrous oxide and 0.5 MAC of isoflurane, 50% nitrous oxide and 1.0 MAC of isoflurane or 1.0 MAC of isoflurane without nitrous oxide[16] at normocapnia. Results are presented as mean (SEM) ($n=5$ in each group).

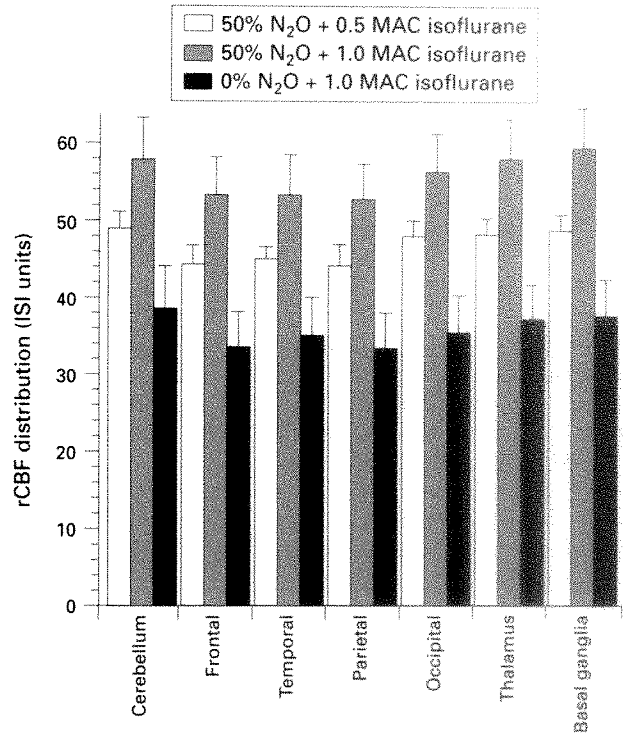

*Figure 2* Regional cerebral blood flow (rCBF) (ISI units) during anaesthesia with 50% nitrous oxide and 0.5 MAC of isoflurane, 50% nitrous oxide and 1.0 MAC of isoflurane or 1.0 MAC of isoflurane without nitrous oxide[16] at normocapnia. Values represent regional distribution recalculated to absolute values (see methods) and are presented as mean (SEM) ($n=5$ in each group).

### EFFECTS OF NITROUS OXIDE AND ISOFLURANE ON THREE-DIMENSIONAL CBF DISTRIBUTION

Nitrous oxide and 0.5 or 1.0 MAC of isoflurane anaesthesia resulted in a pattern with an inhomogeneous CBF distribution ($F=61.6$, $P<0.0001$). During nitrous oxide and isoflurane anaesthesia, the regions with the highest relative CBF were the thalamus, basal ganglia and cerebellum (10% greater than average) followed by the pons (7–10% greater than average). This distribution did not differ from that found during anaesthesia with 1 MAC of isoflurane.[16] rCBF distributions are presented in figure 1.

Absolute rCBF values throughout the same regions were calculated from the two- and three-dimensional blood flow measurements, and are presented in figure 2, together with rCBF values obtained when isoflurane was administered alone.[16]

## Discussion

We have found that anaesthesia during normocapnia with 50% nitrous oxide and 0.5 or 1.0 MAC of isoflurane resulted in a global CBF of 44 and 53 ISI units, respectively. These values were significantly higher compared with a global CBF value of 33 ISI units obtained with 1.0 MAC of isoflurane without nitrous oxide under otherwise identical conditions.[16] This latter CBF value was lower than that in the awake state,[9] which is in accordance with other recent reports[22 23] and contradicts the previous common opinion that isoflurane increases CBF. In contrast, inhalation of 50% nitrous oxide in healthy young men increased global CBF from 55 to 67 ml 100 $g^{-1}$ $min^{-1}$ during normocapnia.[9] This increase in CBF during nitrous oxide administration is in agreement with results from investigations on cortical blood flow in humans.[7 8]

The CBF values found in this study were intermediate between values obtained when nitrous oxide and isoflurane are used alone. The finding that addition of nitrous oxide to a basic anaesthetic increases CBF has been established previously[24 25] using two-dimensional methods. In these studies the effect of nitrous oxide was evaluated by substituting an equipotent dose of volatile anaesthetic in order to maintain an unchanged anaesthetic level. Recent studies have shown that nitrous oxide increases blood flow velocity also when it is added to an otherwise unchanged propofol or isoflurane anaesthesia.[10 11] We found that substituting 0.5 MAC of isoflurane with 50% nitrous oxide increased CBF and that a further, but non-significant, augmentation occurred when the concentration of isoflurane was increased to 1 MAC. Hence, the nitrous oxide-induced effect on blood flow is not attenuated by increasing anaesthetic depth with isoflurane up to 1 MAC. The finding that CBF tended to be higher when the isoflurane concentration was doubled may be explained by a direct vasodilator effect on vascular smooth muscle, caused by increased isoflurane concentrations.[26]

We have reported previously that the global increase in CBF induced by nitrous oxide alone was distributed unevenly, with the main increase in the frontal, temporal and parietal cortex but also in the basal ganglia, insula and in the thalamic region.[9] The flow pattern gave the impression that inhalation of nitrous oxide augmented flow through regions associated anatomically with the limbic system,[27] probably because of selective activation of these areas.[9] This pattern was entirely different from that seen with isoflurane. During 1 MAC of isoflurane anaesthesia, rCBF distribution showed higher CBF levels in the pons and subcortical structures (thalamus and basal ganglia) compared with the cortex.[16] If nitrous oxide stimulates metabolism in some areas of the brain, the effect might be alleviated by addition of other anaesthetics which depress metabolism.[13 28] This fits well with our present finding that nitrous oxide did not alter rCBF distribution induced by isoflurane anaesthesia.

Isoflurane and halothane induced different patterns of rCBF.[16] The reason for the selective difference in relative flow through different regions during isoflurane and halothane anaesthesia is unknown. The most likely explanation is based on the fact that the normal brain has a tight coupling between brain metabolism and flow[29] and that the two volatile anaesthetics have different effects on metabolism in various parts of the brain. A flow metabolism relationship is evident during both isoflurane and halothane anaesthesia in the rat.[30] Assuming that volatile anaesthetics have different effects on metabolism in various brain regions, together with the observations that addition of nitrous oxide to isoflurane increases CBF uniformly and that nitrous oxide has no effect on isolated cerebral arteries,[9] we conclude that our study supports the hypothesis that nitrous oxide exerts an indirect vasodilator effect in the brain.[31] Identification of the mediator(s) of this vasodilator effect merits further investigation.

# Self-learning fuzzy logic control of neuromuscular block

J. J. ROSS, D. G. MASON, D. A. LINKENS AND N. D. EDWARDS

## Summary

We have assessed the performance of a "self-learning" fuzzy logic controller to administer atracurium to a required depth of neuromuscular block. We studied 20 ASA I and II patients undergoing surgery anticipated to last longer than 90 min. A Datex Relaxograph was used to measure the degree of neuromuscular block, and control to a T1 twitch height set point of 10% of baseline neuromuscular function was selected. The controller commenced with a blank rule-base and instructed a Graseby 3400 infusion pump to administer an atracurium infusion to maintain this level of block. The system achieved stable control of neuromuscular block with a mean T1 error of −0.52% (SD 0.55%) accommodating a range in mean atracurium infusion rate of 0.25–0.44 mg kg$^{-1}$ h$^{-1}$. These results compare favourably with the more computationally intensive and unwieldy adaptive control strategies for atracurium infusion used previously. There was less variation in infusion rates than in our previously studied fixed rules fuzzy controller. (*Br. J. Anaesth.* 1997; **78**: 412–415).

**Key words**
Neuromuscular block, atracurium. Computers, fuzzy logic.

Provision of reliable neuromuscular block is an important part of modern anaesthetic practice. Newer agents provide rapid onset of dense yet short-acting block providing good conditions for surgery. However, these agents require careful monitoring to reduce the incidence of clinically significant fluctuations in the density of block, and allow rapid offset at the end of surgery. In longer operations multiple incremental doses of neuromuscular blocking agents may be required. Neuromuscular block therefore lends itself to control by continuous drug infusion, but pharmacokinetic and pharmacodynamic differences between patients makes selection of an appropriate infusion rate to maintain the desired level of block difficult.[1]

Closed-loop control provides the ability to maintain stable neuromuscular block while allowing for variation in the individual's response to the drug. This benefits the patient in that the minimum quantity of drug is administered and the clinical workload is reduced, allowing more time to be spent on other aspects of anaesthesia. The reliability of neuromuscular block monitoring with electromyography permits a precise control strategy to be implemented. Various controllers have been demonstrated in the past, from simple on–off type to complex model-based controllers.[2–11] We have demonstrated previously the use of fuzzy logic in the control of neuromuscular block with a fixed rule-base. While this controller provided accurate control of neuromuscular block, we noted considerable variation in blocker infusion rate.[12 13] In addition, such a controller is not adaptive and it is difficult to deduce a general fixed rule to accommodate individual variations between patients. These problems may be overcome by adding a self-learning facility to the controller. Such a controller has been demonstrated previously only in computer simulation.[14 15] This is the first study investigating the clinical use of self-learning fuzzy logic control.

## Patients and methods

The study was approved by the local Ethics Committee and 20 adult ASA I or II patients undergoing surgery anticipated to last longer than 90 min gave written informed consent.

The closed-loop system comprised a general purpose IBM compatible computer (PC) interfaced to a Datex Relaxograph and a Graseby Medical 3400 infusion pump. The PC was programmed to use the "self-learning" fuzzy logic control strategy and coordinate communication via serial links. The system was tested actively by computer simulation in "worst-case" and "noisy-signal" scenarios, and a further check on the adequacy of patient response was implemented to eliminate the possibility of erroneous controller outputs arising should the patient not receive atracurium, for example the infusion catheter became blocked or disconnected. A hierarchical alarm structure was used to deal with alarm conditions appropriately. System hardware and software integrity were tested in real-time using a simulation device attached to the Relaxograph.[16]

Patients received a standard anaesthetic. Anaesthesia was induced with alfentanil 10 μg kg$^{-1}$ and a sleep dose of propofol, followed by an infusion of 10 mg kg$^{-1}$ h$^{-1}$. The patient's lungs were ventilated

Correspondence to N. D. E.

manually with 67% nitrous oxide in oxygen while the automated atracurium delivery system was set up. One arm was placed supine on an extension board and secured with tape. MSB unilect silver–silver chloride electrodes were placed on skin previously cleansed with alcohol solution. The two stimulating electrodes were placed over the ulnar nerve distribution in the forearm, the recording electrodes were placed one on the hypothenar eminence and one at the base of the fifth metacarpal, and the ground electrode was placed on the radial side of the forearm at the wrist. The Relaxograph was then calibrated and set to deliver a train-of-four supramaximal stimulus every 20 s. The Relaxograph was observed for at least 3 min before neuromuscular block was commenced to ensure a stable baseline. We used the first response to train-of-four (T1) as the end-point for monitoring and control. A T1 set point at 10% of baseline was chosen. A filename was entered for data storage and the concentration of atracurium (2 mg $ml^{-1}$) entered so that the computer could convert the controller output from a mass rate to a flow rate, that is ml $h^{-1}$. The patient's weight was entered to enable the loading dose of 0.33 mg $kg^{-1}$ to be calculated, which it then delivered at 1200 ml $h^{-1}$ to facilitate tracheal intubation. Anaesthesia was maintained with propofol 8–10 mg $kg^{-1}$ $h^{-1}$, the patient's lungs ventilated mechanically with oxygen and nitrous oxide, and morphine was administered as appropriate. The fuzzy logic controller maintained neuromuscular block throughout. Recovery of T1 was monitored every 20 s, giving an indication of patient sensitivity to the drug, allowing the controller to create its first control rule. Thus, for instance, if recovery was rapid, a high initial infusion rate was selected as T1 approached 10%, to a maximum rate of 100 mg $h^{-1}$. If T1 failed to decrease below the 10% set point, the computer was programmed to deliver an additional 5-mg bolus and repeat as necessary until T1 was less than 10%. The fuzzy controller commenced operation when T1 had recovered to between 5% and 10%. To reduce spurious data from noisy signals the median of the previous three readings was used. This median T1 value, calculated each 60 s, was then used for action by the controller. In addition, the supervising anaesthetist could administer an atracurium bolus should neuromuscular block be inadequate, alter the T1 set point or quit the programme as required.

The performance of the fuzzy controller was analysed by raw T1 values. T1 errors (measured T1 value − the set point T1 value) were analysed for mean and root mean square deviation (RMSD) for the entire duration of control. In addition, these values were determined for the initial 30 min of control to allow comparison with our previous controller.[12] Mean (SD) atracurium infusion rates delivered every 1 min during control in each individual case were also calculated and then summarized for all 20 patients as mean (SD) and range.

## Results

We studied 20 patients, mean age 43 (range 25–73) yr and mean weight 67 (48–85) kg. Mean duration of control was 75 (46–143) min. Tables 1 and 2 show the control performance indices for both total duration of control and for the first 30 min of control. The mean T1 error from set point was −0.52% (SD 0.55%; range −1.94 to +0.37%) for the total duration of control, and −0.74% (0.73%; −1.80 to +0.90%) for the first 30 min of control. The variation about this mean was low, with a mean SD of 2.3% (0.62%; 1.00–3.61%) for the total duration of

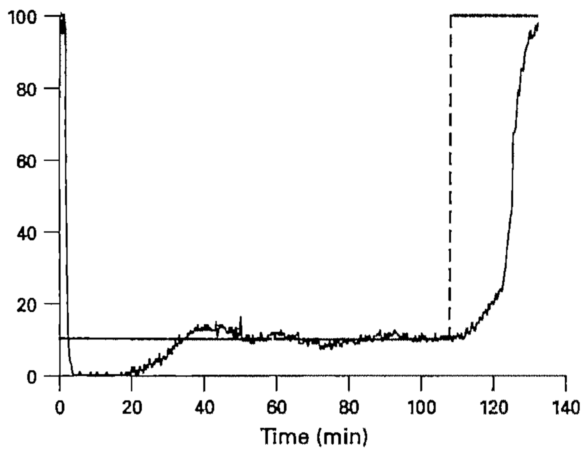

*Figure 1* Sample clinical trace obtained with self-learning fuzzy controller showing stable neuromuscular block at the 10% level over 75 min. ——=Desired T1 value, ——=raw T1 values.

control and 2.51% (0.75%; 1.20–5.00%) for the first 30 min. Mean RMSD values were similar to the mean SD, being 2.39% (0.66%; 1.10–3.69%) for the total duration of control, and 2.69% (0.73%; 1.40–5.10%) for the first 30 min, confirming that mean error was close to zero. Figure 1 shows a sample clinical trace.

Mean atracurium requirements varied from 0.25 to 0.44 mg kg$^{-1}$ h$^{-1}$ for the total duration of control and from 0.27 to 0.48 mg kg$^{-1}$ h$^{-1}$ for the first 30 min. The SD of the infusion rates of atracurium delivered over the period of control gives an indication of the variation in infusion rate for that period in each patient. The mean SD atracurium infusion rate was 0.14 mg kg$^{-1}$ h$^{-1}$ for the total duration of control and 0.16 mg kg$^{-1}$ h$^{-1}$ for the first 30 min. In all cases good operating conditions prevailed throughout and all neuromuscular block was antagonized easily at the end of surgery. No patient required a bolus dose of atracurium to maintain adequate neuromuscular block.

## Discussion

Fuzzy logic is an appropriate, simple and effective technique for controlling non-linear and unpredictable processes, dealing in imprecise, qualitative (i.e. "fuzzy") terms such as "low", "medium" or "high" rather than precise measurements.[17 18] This imprecision permits very simple but effective control rules to be generated which are easy to modify and update rapidly in real-time. Fuzzy logic control is intrinsically suited to the control of physiological processes because it requires little hard input data before it can begin functioning, unlike other strategies such as "neural networks".

For closed-loop control of neuromuscular block the following features need to be addressed when designing the system: recognition of the onset and, more importantly, the rate of decay of neuromuscular block; recognition of the difference between desired and actual T1 value (error); recognition of the rate of change in error from the desired T1 value; and elimination of drift from the desired T1 value when achieved, that is steady state error.

Using a fixed rule-base, we have demonstrated previously that fuzzy logic control is appropriate for controlling neuromuscular block.[12] However, the development of such a controller required the construction of a hand-crafted rule-base which was time and labour intensive. However, by incorporating a "self-learning" layer to the fuzzy controller, it becomes self-teaching in real-time in the clinical situation and dispensed with the need for a pre-set fixed rule-base. Our self-learning controller starts with a blank rule-base, and this is the first study to investigate the clinical application of such an intelligent control technique.

The "self-learning" strategy implemented in our controller functioned by rapidly and repeatedly measuring T1 twitch height and modifying the atracurium infusion rate. This allowed the controller to recognize the patient's drug requirements and select infusion rates appropriate to maintain 90% neuromuscular block. Initially, the fuzzy rule-base is completely blank as the controller is unaware of its first rule until control begins. This first rule is simple and generated by assessing the return of neuromuscular tone towards the desired T1 height. The effect is then assessed and adapted by generating new rules as control continues. This is achieved by adding a performance index which measures the error from a desired trajectory and modifies recently generated control rules so making the controller self-learning. In addition an ageing process was added to the rules generated so that those recently generated carried more weight, or were considered "more relevant" than older rules. This helps eliminate steady state error and continually improves controller performance.

The results of this study showed improved performance over previous controllers. Control was as good as our previous fixed-rule controller with less erratic infusion rates being demanded; the controller delivered a mean SD atracurium infusion rate of 0.16 mg $kg^{-1}$ $h^{-1}$ for the first 30 min compared with 0.23 mg $kg^{-1}$ $h^{-1}$ in our previous study.[12] Control was implemented with a basic amount of information. At no point did the controller have to administer a bolus in order to regain control of a deteriorating situation and in no case was a diverging or progressively unstable oscillation entered.

While fuzzy logic has been used in other fields in anaesthesia[17–19] this is the first occasion where, by application of a self-learning facility to the fuzzy logic controller, a physiological process during anaesthesia has been controlled entirely by machine alone. The controller determined individual drug requirements and administered atracurium accurately in each case, demonstrating the ability to assess and respond to fluctuating patient conditions during surgery. The success of this self-learning control system should encourage research into the control of other physiological processes.

REVIEW ARTICLE

# Congenital heart disease in adults

D. FINDLOW AND E. DOYLE

Congenital anomalies of the heart and cardiovascular system occur in 7–10 per 1000 live births (0.7–1%).[113] It is the commonest form of congenital disease and accounts for approximately 30% of the total burden of congenital disease. With a decline in the incidence of rheumatic heart disease, congenital heart disease has become the main cause of heart disease in children in the developed world; 10–15% of affected children have associated congenital anomalies of the skeletal, genitourinary or gastrointestinal systems. Approximately 10–15% of patients with congenital heart disease may survive untreated to adulthood but the majority require some form of cardiac surgery as children. Nine lesions comprise more than 80% of congenital heart disease while a wide range of more unusual and complex lesions comprise the remainder.

*Table 1* Incidence of common congenital heart defects[66]

| | |
|---|---|
| Acyanotic lesions | |
| Ventricular septal defect | 35% |
| Atrial septal defect | 9% |
| Patent ductus arteriosus | 8% |
| Pulmonary stenosis | 8% |
| Aortic stenosis | 6% |
| Coarctation of the aorta | 6% |
| Atrioventricular septal defect | 3% |
| Cyanotic lesions | |
| Tetralogy of Fallot | 5% |
| Transposition of the Great Arteries | 4% |

Surgical closure of a patent ductus arteriosus was first performed in 1939.[53] In 1945 the first surgical repair of coarctation of the aorta was reported[27 54] and the Blalock–Taussig shunt from the left subclavian to the left pulmonary artery was introduced as a palliative procedure for tetralogy of Fallot[12] allowing patients with this lesion to live for several decades. In 1955 a series of patients who underwent successful open heart surgery with cardiopulmonary bypass to correct septal defects was reported.[75]

Advances in cardiological diagnosis and management, surgical techniques, anaesthesia and intensive care have resulted in a situation where the majority of conditions are operated up on with a high proportion of medium-term survivors. It has become increasingly apparent that few of these procedures are corrective, resulting in a totally normal heart, but that the majority are palliative to a greater or lesser extent and that there are long-term residual effects from these procedures. The ligation and division of an asymptomatic patent ductus arteriosus is closest to a complete cure. Consistent features of surgery for congenital heart disease include low early mortality, good medium term survival with a high proportion of asymptomatic patients but a high incidence of longer term problems relating to the original condition and to the pathophysiological effects of the operative procedure. These may only become apparent in an exercising or stressed patient as occurs during trauma, infection, surgery or the postoperative period.

A large cohort of patients with treated congenital heart disease is now surviving into adult life. Ideally these patients should undergo regular review by a cardiologist to detect developing problems but this may fall by the wayside as adolescents become adults, move home, travel and assert independence by defaulting on appointments. There are profound implications for these people in relation to life insurance, employment prospects, genetic counselling, pregnancy and exercise. These individuals now approaching adolescence and adult life may require anaesthesia for elective and emergency surgery, trauma and childbirth. They have traditionally returned to paediatric cardiac centres for noncardiac surgery but as they become adults this is not feasible and they must be anaesthetized in adult hospitals. Cardiovascular impairment in these patients is generally the result of one or more pathophysiological processes which are the result of a multitude of anatomical abnormalities. These are arrhythmias, hypoxaemia, pulmonary disease and ventricular dysfunction.

In the past, unoperated significant congenital heart disease in adults was not uncommon but it is now unusual for this to be seen, and some form of correction or palliation is usually performed in childhood or adolescence. Those untreated lesions which may be seen in adults will have initially caused few or no symptoms but these develop in later life because of calcification of abnormal valves, onset of arrhythmias,

progressive ventricular dysfunction, pulmonary hypertension or infective endocarditis. Patients who undergo insertion of artificial patches, conduits or valves as children usually deteriorate and require reoperation when older because of lack of growth and structural deterioration of the implant.

## General considerations

### ARRHYTHMIAS

Arrhythmias are possibly the commonest problem in long-term survivors of surgery for congenital heart disease. Atrial arrhythmias are common after atrial surgery and in the presence of atrial distension, as after a Fontan procedure. Right ventriculotomy entails damage to conducting tissue and often results in a right bundle branch block pattern in the ECG. This is usually asymptomatic but when combined with left bundle damage resulting in left bundle hemiblock may progress to complete heart block. Preoperative 24-h ambulatory ECG recording is indicated in symptomatic patients undergoing elective surgery.

### HYPOXAEMIA

Residual hypoxaemia may be caused by decreased pulmonary perfusion with residual right-to-left shunts or by pulmonary hyperperfusion. With limited or obstructed pulmonary blood flow, strategies to avoid further hypoxaemia during anaesthesia include ensuring adequate hydration, maintaining systemic arterial pressure (to minimize right-to-left shunting), minimizing increases in pulmonary vascular resistance (hypocapnia, alkalosis, hyperoxia, low mean airway pressure) and avoiding sudden increases in oxygen requirements caused by inadequate anaesthesia. In the case of pulmonary hyperperfusion with mixing of systemic and pulmonary venous blood, increases in the pulmonary to systemic flow ratio (*Qp*/*Qs*) either increase cardiac work or, if ventricular function is already maximal, decrease systemic perfusion. Persisting left-to-right shunts also predispose to chest infections and worsening of existing ventilation–perfusion abnormalities. Theoretical considerations suggest that in the presence of a right-to-left shunt, inhalation induction of anaesthesia is slower and intravenous induction more rapid than normal while left-to-right shunts have opposite effects. In practice these factors have no significant clinical effect on induction of anaesthesia.

Hypoxaemia results in polycythaemia, limitation of maximal exercise capacity and a tendency to vascular thrombosis. The ability to increase cardiac output in response to exercise or stress is reduced. Possible mechanisms for myocardial dysfunction include recurrent episodes of severe hypoxaemia, decreased coronary perfusion pressure secondary to systemic pulmonary artery shunting and increased blood viscosity leading to microvascular occlusion. These factors result in myocardial ischaemia and fibrosis and these changes are a common post-mortem finding even in affected infants. Ultimately, ventricular diastolic compliance is reduced and a greater ventricular end-diastolic volume is required to maintain stroke volume, resulting in reduced myocardial reserve or ventricular failure. Children undergoing correction of hypoxic lesions such as tetralogy of Fallot after 2 yr of age commonly have normal left ventricular function at rest but reduced ability to increase cardiac output in response to exercise,[15] suggesting that chronic hypoxaemia is associated with irreversible myocardial damage.

Polycythaemia is the main adaptive response to chronic hypoxaemia and is necessary to provide adequate tissue oxygenation. Red cell mass may be up to three times normal and blood volume may exceed 100 ml $kg^{-1}$. A normal haemoglobin concentration during an acute illness may indicate bleeding or iron deficiency. Dehydration and loss of extracellular fluid aggravates this tendency. Blood viscosity is increased and associated with an increased risk of thrombosis and intracranial haemorrhage. Hypoxaemia and polycythaemia are associated with abnormal haemostasis in patients with congenital heart disease. The aetiology of this effect is unclear but includes thrombocytopenia, platelet dysfunction, hypofibrinogenaemia, accelerated fibrinolysis and factor deficiencies. Patients may exhibit easy or spontaneous bruising, epistaxis and haemoptysis. Prolongation of the bleeding time, thrombin time and partial thromboplastin time may be seen. Aspirin, non-steroidal anti-inflammatory drugs and heparin may exacerbate these effects. The risk of excessive perioperative bleeding is increased.

### PULMONARY HYPERTENSION

Unrestricted left-to-right shunts which result in increased pulmonary blood flow prevent the normal postnatal decreases in pulmonary blood flow, pulmonary vascular resistance and pulmonary artery pressure. Examples of this include large unrestrictive ventricular septal defects, atrioventricular canal defects, transposition of the great arteries with ventricular septal defect and a large patent ductus arteriosus. These lesions produce pulmonary hypertension and right ventricular hypertrophy early in life. If this situation continues there is the development of irreversible pulmonary hypertension which in many cases does not regress fully after surgical repair. The desire to prevent the development of irreversible pulmonary hypertension is one of the reasons for progressively earlier definitive repair of these lesions being undertaken. Even after repair a patient with significant preoperative pulmonary hypertension may present problems when undergoing non-cardiac surgery under general anaesthesia. With other lesions such as untreated atrial septal defect where pulmonary flow is increased and pressures are normal, pulmonary vascular disease takes decades to develop and is rarely an issue in the post-repair management of anaesthesia.

The aim in patients at risk is to maintain right ventricular performance in the face of increased right ventricular afterload. Predisposing factors should be avoided and this may also reverse any reversible component to the hypertension. These include hypoxaemia and hypercapnia, acidosis, atelectasis, hyperinflation or physical compression of the lungs. Patients should be adequately premedicated and anaesthetized to avoid unnecessary sympathetic stimulation. Whenever possible regional anaesthetic techniques are suitable in these circumstances to avoid predisposing factors. For all but the briefest cases performed under general anaesthesia, tracheal intubation and intermittent positive pressure ventilation should be used to ensure adequate oxygenation and avoid hypercapnia and acidosis. Mild respiratory alkalosis should be produced. Adequate depth of anaesthesia before intubation is essential to avoid reflex pulmonary vasoconstriction. After operation, the same principles apply and also include measures to provide adequate analgesia. Preload may be assessed by central venous pressure monitoring, and the use of a pulmonary artery catheter (if the anatomy allows) is useful and permits accurate measurements and evaluation of treatment during anaesthesia and the postoperative period in patients at risk. Inotropic support of the heart may improve right ventricular performance until the situation improves and vasodilators with a degree of selectivity for the pulmonary circulation such as tolazoline and prostacyclin are effective pulmonary vasodilators,[95 106] although the disadvantages of systemic hypotension and thrombocytopenia have limited their use. Recent interest in the use of inhaled nitric oxide as a pulmonary vasodilator in several conditions has been rewarding and this is now a valuable treatment for pulmonary hypertension. It is particularly useful to have a treatment which does not simultaneously lower systemic vascular resistance and increase the degree of right-to-left shunting. Nitric oxide, in concentrations up to 80 parts per million, has been used to treat pulmonary hypertension in congenital heart disease,[98] after cardiac surgery,[98 122] in primary pulmonary hypertension,[91] persistent pulmonary hypertension of the newborn[69 99] and the adult respiratory distress syndrome.[102]

### SHUNTS

Classical Blalock–Taussig shunts performed using the subclavian artery result in loss of radial pulsation in the left arm and the inability to measure arterial pressure here or insert an intra-arterial cannula. Occasionally patients have a classical or modified Blalock–Taussig shunt as the only or main source of pulmonary perfusion. In this case pulmonary perfusion and oxygenation of blood depends on the physical characteristics of the shunt, mainly its length and diameter. As these are fixed and pulmonary artery pressure is usually low relative to systemic arterial pressure, pulmonary blood flow is dependent primarily on systemic arterial pressure which drives blood through the shunt. These patients are hypoxaemic and polycythaemic with a predisposition to thrombosis. Measures which lower systemic arterial pressure or systemic vascular resistance may have disastrous effects on pulmonary perfusion and should be used with caution.

### THROMBOSIS AND EMBOLI

In patients with residual connections between the right and left sides of the heart, paradoxical embolism of air or clot to the central nervous system, mesenteric circulation, renal circulation and skeletal vessels may occur during anaesthesia and surgery. Thromboses may occur during the postoperative period and are particularly worrying if there are areas in the heart likely to cause thrombus or if there is a significant right-to-left shunt.

### ANTIBIOTIC PROPHYLAXIS

Infective endocarditis remains a risk after pulmonary or aortic valvotomy, repair of tetralogy of Fallot and most complex operations, especially if artificial material is inserted. It is not a risk after simple repair of atrial septal defect, ventricular septal defect or patent ductus arteriosus. The risk is present during delivery, and labouring women with relevant lesions should receive antibiotic prophylaxis until after delivery.

### ANAESTHETIC TECHNIQUE

In many cases where there has been a good outcome from cardiac surgery and where there is no evidence of late deterioration, conventional anaesthetic management is suitable. In more complex cases with functional limitation, the details of the anaesthetic technique chosen are likely to be less important than the care with which the patient is managed. Modification of the anaesthetic technique to take account of the main problems currently presented by the patient is required. In general, adequate premedication is desirable to avoid anxiety and tachycardia. Slow incremental induction of general anaesthesia and the avoidance of myocardial depression, vasodilatation and hypotension are particularly important in patients where there is myocardial dysfunction or where myocardial performance is critically dependent on preload, as in cavo–pulmonary anastomoses and some atrial switch procedures. In most compromised patients undergoing general anaesthesia, tracheal intubation and intermittent positive pressure ventilation should be used for all but the shortest procedures to avoid the potential complications of transient hypoxaemia or hypercapnia and respiratory acidosis. There should be a low threshold for the use of invasive cardiovascular monitoring, although this may be difficult to perform if there has been previous cannulation of arteries and central veins. Invasive monitoring of central venous pressure is particularly valuable in detecting changes in preload and for guiding fluid replacement in those patients who require a high central venous pressure to ensure pulmonary perfusion or who have a morphological pulmonary ventricle acting as the systemic ventricle. It is also valuable for similar reasons during central neuraxial regional techniques. An arterial catheter provides continuous arterial pressure measurement in patients who may suffer arrhythmias, increased right-to-left shunting and hypoxaemia or reduced cardiac output if arterial pressure decreases with hypovolaemia or vasodilatation.

Regional anaesthetic techniques should be considered alone and combined with general anaesthesia whenever possible. In many circumstances the opportunity to avoid general anaesthesia and perform the proposed procedure in an awake or lightly sedated patient will avoid many potential problems. The excellent postoperative analgesia which is often a feature of regional techniques reduces cardiovascular stress and the release of catecholamines, which may cause arrhythmias and pulmonary vasoconstriction. There is considerable evidence from obstetric practice that lumbar extradural block may be performed safely even in severely compromised patients if the block is produced slowly and incrementally, invasive monitoring is used to guide fluid administration and vasodilatation and hypotension are avoided.

## Specific conditions

### PATENT DUCTUS ARTERIOSUS

Ligation of a small patent ductus arteriosus in an asymptomatic child is probably the only surgical procedure for congenital heart disease which results in an entirely normal individual without any long-term complications. An untreated small patent ductus arteriosus has a mortality of more than 40% by the age of 50 yr and is prone to bacterial endocarditis (more accurately endarteritis of the pulmonary artery). A larger duct often results in increased pulmonary vascular resistance and volume overload of the left ventricle. These changes may not entirely regress after ligation of the duct and there may be long-term pulmonary hypertension. Ducts may also be closed via the transvenous route using a cardiac catheter.[6]

### ATRIAL SEPTAL DEFECT

The ostium secundum form of atrial septal defect is caused by failure of closure of the foramen ovale. The majority of cases are detected in childhood and repaired before any long- term sequelae develop. If untreated the risks of death are 25% by 27 yr, 50% by 36 yr, 75% by 50 yr and 90% by 60 yr.[18] The long-term prognosis after repair is excellent. In patients without arrhythmias before closure there is a low incidence of late postoperative arrhythmias (5–10%). In patients treated after the onset of atrial fibrillation or flutter, these rhythms reappear in virtually all patients by 25 yr after repair. More rarely nodal bradycardias or complete heart block may occur. Endocarditis does not occur on the repaired defect and is seen only if there are associated left-sided anomalies such as a cleft mitral valve.

Atrial septal defects which have appropriate anatomical features especially an adequate rim of septal tissue, may be repaired by a transvenous approach in the cardiac catheter laboratory using a clamshell transcatheter device.[16] This avoids the need for sternotomy and cardiopulmonary bypass and may prove superior in long-term follow-up studies. These devices become covered in endothelium, and antibiotics for the prophylaxis of endocarditis are not subsequently required unless there is a residual defect with exposed foreign material or a residual defect and shunt with turbulent blood flow. There are currently no data comparing the incidence of long-term complications after the two procedures.

### VENTRICULAR SEPTAL DEFECT

Ventricular septal defect is the commonest congenital cardiac malformation (35%) and occurs both as an isolated defect and as part of more complex anomalies. They are most commonly of the membranous or perimembranous type and lie posterior and superior to the crista intraventricularis in what would be the membranous portion of the ventricular septum. The bundle of His lies at the posterior margin of this defect and may be damaged during surgical repair. In 10% of isolated congenital ventricular septal defects there are multiple defects in the muscular portion of the septum. These may be seen in an adult after repair of a membranous ventricular septal defect as they are difficult to close completely at the time of surgery because of heavy trabeculation on the right ventricular aspect of the interventricular septum. As these muscular lesions are small they rarely lead to increased right ventricular or pulmonary artery pressure and leaving them unrepaired may be safer than persisting with attempts at closure. Persisting defects of this nature carry the risk of endocarditis and systemic paradoxical embolism of air or clots during the perioperative period. Occasionally, a small asymptomatic ventricular septal defect is left unrepaired (maladie de Roger) and this does not have any haemodynamic consequences but the risk of endocarditis and paradoxical embolism remains.

Traditional surgical closure of a ventricular septal defect via a right ventriculotomy is associated with an incidence of 15–100% of subsequent conduction abnormalities, especially right bundle branch block and left axis deviation.[51 87] Progression to third-degree (complete) atrioventricular block may occur especially if there was a transient period of complete heart block in the early postoperative period.[51] Ventricular ectopics and ventricular tachycardia may also occur. The incidence of these problems is lower in patients who have undergone closure of a ventricular septal defect via a right atrial approach rather than via a right ventriculotomy but they may still occur presumably because of damage to the right bundle close to the defect.[87] Pulmonary hypertension may not regress completely after repair in affected patients and particularly during exercise this may become severe so that ultimately pulmonary vascular disease becomes established and irreversible.

### AORTIC STENOSIS

This comprises 5% of congenital heart disease and is found in association with other lesions, especially coarctation of the aorta, in approximately another 5%. Aortic valve replacement in children is fraught with difficulty and is avoided whenever possible. Because of this, treatment is usually by means of an aortic valvotomy. This procedure results in improvement of the stenosis but usually at the price of some degree of regurgitation. Symptoms tend to recur as the child grows and valve replacement may eventually be necessary because of this or worsening aortic regurgitation. Patients may be well for many years until deterioration occurs and may undergo anaesthesia along the same principles as older patients with aortic valve disease. Endocarditis remains a significant risk.

### PULMONARY STENOSIS

This condition comprises approximately 8% of congenital heart disease. Treatment in severe cases was by open valvotomy but in recent years this has been replaced by balloon valvuloplasty.

### TETRALOGY OF FALLOT

The tetralogy of Fallot consists of a large ventricular septal defect with right ventricular outflow tract obstruction which is either valvular, infundibular or both. The two other features which make up the tetralogy are right ventricular hypertrophy and overriding of the interventricular septum by a dilated aorta. Although this lesion is compatible with survival to adulthood, the majority of cases are detected and repaired in childhood.

Traditional surgical management of tetralogy of Fallot was by means of a systemic pulmonary artery Blalock–Taussig shunt in symptomatic neonates and infants, followed by definitive repair at 2–5 yr of age or in asymptomatic patients definitive repair at the same stage with no prior shunt. Surgical correction consists of closure of the ventricular septal defect and relief of the pulmonary stenosis. This is usually performed by incision of the right ventricular outflow tract and pulmonary artery, resection of hypertrophic muscle bands and, if necessary, placement of a transannular patch of pericardium or Dacron over the incised pulmonary valve ring and proximal pulmonary artery. Recently, transatrial repair has been developed where, if the anatomy is appropriate, the ventricular septal defect may be closed via the right atrium without the need for a ventriculotomy. The two-stage policy is associated with the problems of chronic hypoxaemia for several years, right ventricular hypertrophy leading to subsequent ventricular dysfunction and the potential complications of a Blalock–Taussig shunt which include shunt failure, pulmonary artery narrowing, pulmonary artery distortion and the development of pulmonary artery vascular occlusive disease.

In order to avoid these problems definitive correction in infancy has now become common and can be achieved with a low mortality in infants of less than 12 months.[21 56 117] This approach avoids the need for two cardiac operations and eliminates the complications of pulmonary artery shunting. In the fetus with tetralogy of Fallot the right ventricle functions against placental resistance as normal and there is a normal right ventricular pressure and compliance despite right ventricular outflow tract obstruction. Successful repair early in life, therefore, has the potential to avoid the development of right ventricular hypertrophy and dysfunction which is implicit in tetralogy of Fallot. There is also the theoretical advantage that this aggressive approach may minimize secondary damage to heart, lungs and brain of a prolonged period of chronic hypoxaemia until definitive repair. Early correction is considered to improve cumulative survival, reduce complications and enhance later quality of life with better late results than repair performed in later childhood.[15 120] The incidence of late ventricular arrhythmias is certainly lower in patients who undergo repair early in life. This is probably related to the progressive right ventricular hypertrophy and fibrosis which develops in uncorrected tetralogy of Fallot.[30] An initial palliative shunt in infancy followed by definitive repair several years later is still indicated in symptomatic patients of weight less than 3 kg, the presence of major associated anomalies or unfavourable patterns of pulmonary artery anatomy.

The results of surgery are generally good with most patients attaining near normal functional capacity.[58 59 129] The overall 30-yr survival rate in hospital survivors for a large series was 86% compared with a rate of 96% in a control population. Intracardiac repair performed at more than 12 yr of age carries a significantly worse prognosis than earlier repair.[83] Late sequelae include supraventricular tachyarrhythmias, ventricular arrhythmias,[57] right-sided heart failure resulting from ventriculotomy, pulmonary regurgitation and reduced exercise tolerance.[20 83 100]

Evaluation of pulmonary function 13–26 yr after surgery in 68 patients who had undergone definitive intracardiac repair of tetralogy of Fallot demonstrated moderately reduced work capacity and lung function. In particular, forced vital capacity, maximum voluntary ventilation and symptom-limited work capacity were approximately 80% of predicted.[65] Other long-term follow-up studies have demonstrated reduced exercise tolerance, reduced diffusing capacity, increased physiological dead space and increased alveolar–arterial oxygen tension differences after late definitive repair possibly secondary to pulmonary vascular disease.[115 123] There was no tendency to normalization of work capacity or lung function over two decades of follow-up. Exercise capacity tends to be related inversely to age at the time of definitive repair.[60] A late age at repair implies several years of pulmonary hypoperfusion which may have contributed substantially to the pulmonary damage and this may not occur in patients currently undergoing early definitive intracardiac repair. Residual pulmonary regurgitation with increased right ventricular stroke volume after repair is strongly correlated with reduced vital capacity and respiratory reserve and with reduced exercise capacity.[103 124] Patients who had not undergone palliative Blalock–Taussig shunt had better lung function at follow-up than those who had, but the shunt may not have been the entire cause of reduced lung function as shunted patients tend to be smaller with more severe disease. Reduced lung function associated with Blalock–Taussig shunts may be caused by hypoplasia of the lung, impaired ventilatory mechanics, hypoperfusion, increased blood viscosity, thrombosis and occlusion of small vessels. Alternatively there may be pulmonary hyperperfusion through a shunt which is too wide causing intimal thickening and pulmonary hypertension.

Cardiac output in relation to oxygen consumption was reduced in 74% of patients during exercise, and symptom-limited exercise tolerance was 87% of predicted.[64] Right ventricular pressure was uniformly high during exercise compared with normal. Work capacity is affected adversely by right ventricular hypertension and pulmonary regurgitation. Residual right ventricular hypertension is associated with ventricular arrhythmias and late sudden death.[46 80] The use of a transannular patch to relieve right ventricular outflow tract obstruction is significantly associated with a high incidence (58%) of pulmonary regurgitation, right ventricular dilatation and dysfunction. These features are strongly correlated with decreased exercise capacity.[20 80]

Arrhythmias are common after repair as a consequence of the proximity of the conduction system to the operative field. There is an increased risk of sudden death and this occurs in 0.3–5% of subjects by 16 yr after operation.[22 30 46 120 129] Ventricular ectopics are present in 40–50% of adult survivors of tetralogy of Fallot repair. The frequency and complexity of ventricular ectopics increases with increasing age.[100] Risk factors for ventricular ectopics are older age at the time of repair, incomplete palliation as demonstrated by right ventricular pressure or volume overload, ventricular dysfunction and pre-existing arrhythmias. Supraventricular and ventricular arrhythmias were found in 72% of patients on 24-h ECG a mean of 14 yr after repair. In 43 asymptomatic patients who underwent exercise testing between 1 and 14 yr after repair, premature ventricular ectopics were recorded during exercise in 23% of subjects; 50% of these had multifocal ventricular ectopics and there were occasional short runs of ventricular bigeminy or of ventricular tachycardia.[60] Ventricular tachycardia occurring after repair of tetralogy of Fallot arises from the ventriculotomy site or from the repaired ventricular septum which are both potential sites of fibrosis and scarring.[57] Right bundle branch block is present in more than 90% of subjects.[120] Left anterior hemiblock combined with right bundle branch block has been reported in up to 10% of subjects after repair. The early prognosis of this combination is favourable but long-term progression to complete heart block is likely.[37] On the basis of these findings it has been suggested that patients undergoing elective surgery should undergo preoperative exercise testing or 24-h Holter monitoring to unmask ventricular arrhythmias so that appropriate treatment may be commenced in patients with frequent episodes. In patients with evidence of advanced atrioventricular block temporary pacing may be advised during the perioperative period. It is clear that after surgical correction of tetralogy of Fallot asymptomatic patients often have significant lesions which may affect cardiac and respiratory function, require surveillance and which may need future interventions.

Patients may occasionally be seen with tetralogy of Fallot who have had a Blalock–Taussig shunt but no subsequent definitive correction. These patients are chronically hypoxaemic and polycythaemic. Some 10% die each 5 yr[32] and the 15-yr mortality in one series of 845 patients was 36%.[59] Life-threatening events include intracerebral abscess in 5%, other cerebrovascular complications particularly thrombotic stroke in 5%, and infective endocarditis in 30%.[32 96]

### TRANSPOSITION OF THE GREAT ARTERIES

Transposition of the great arteries refers to a condition in which the aorta arises from an anatomical right ventricle and the pulmonary artery from an anatomical left ventricle. The transposed aorta usually lies in an anterior plane compared with the pulmonary trunk. The term malposition may be used if there is only one ventricle or if both arteries arise from one of two ventricles. In classical complete transposition the venous connections to the heart are normal. Two parallel circuits exist and uncorrected transposition is incompatible with survival unless there are additional lesions which ensure adequate mixing of oxygenated and deoxygenated blood. The most common of these is a large ventricular septal defect with or without pulmonary stenosis. Initial survival depends on mixing of venous and arterial blood via a natural shunt or an artificial balloon atrial septostomy.

### *Senning and Mustard procedures*

Surgical management of this condition until the 1980s was by means of an atrial switch procedure (Mustard or Senning procedures) in which venous return to the heart is redirected at the atrial level to direct pulmonary blood flow to the right or systemic ventricle and systemic blood flow to the left or pulmonary ventricle.[85 110] The interatrial septum is removed and an intra-atrial baffle created which directs blood from the pulmonary veins across the atrial septal defect to the morphological right ventricle and the systemic arterial circulation. In the Senning procedure the baffle is constructed from native atrial wall while the Mustard operation involves the use of pericardium or foreign material such as Dacron to construct the intra-atrial baffle. Systemic venous blood is directed to the morphological left ventricle and into the pulmonary artery. These procedures are associated with a high incidence of potentially malignant arrhythmias (30–100%), baffle obstruction (10–15%) resulting in systemic venous congestion and pulmonary oedema, and right (systemic) ventricular failure as a consequence of a morphological right ventricle being required to support the systemic circulation.

Long-term follow-up at 16 yr of patients undergoing the Mustard procedure showed a survival of 91% for simple transposition and 60% for complex transposition, respectively. Survival at 16 yr was 78% in both groups for the Senning procedure. Good functional status or lack of symptoms are poor indicators of late outcome after these procedures and close follow-up is required to detect and treat late complications, including right (systemic) ventricular failure, arrhythmias and obstruction to venous return. The Mustard procedure is associated with a higher incidence of late arrhythmias than the Senning procedure.[55] These arise as a consequence of damage to the sinoatrial node or its blood supply, interruption of intra-atrial conduction pathways or damage to the atrioventricular node during an extensive atrial surgical procedure.[49,50] A cohort of 372 survivors of the Mustard procedure had mean resting heart rates that were consistently lower than age-matched controls and a decreasing percentage of subjects in sinus rhythm with time (57% by the end of the eighth post-operative year).[42] In combined surface ECG recording, exercise ECG, Holter monitoring and invasive electrophysiological studies in 87 patients after the Mustard procedure, there was sinus node dysfunction in 47% of patients, ventricular and supraventricular ectopy in 34% and atrioventricular block in 23% although symptoms of conduction disturbances were rare.[10] The commonest disturbance is a nodal rhythm or sinus bradycardia with recurrent episodes of atrial flutter. Supraventricular tachycardia and atrial fibrillation may also occur. There is a high incidence of potentially fatal arrhythmias in survivors of the Mustard procedure during exercise, even in patients without resting symptoms or arrhythmias.[79] Sudden death is common after both procedures and occurs in 5–8% of patients in some series[42] and tachyarrhythmias increase the risk of this event.[47,126] There is failure to increase the ejection fraction of the right (systemic) ventricle during exercise in more than 50% of asymptomatic patients 5–15 yr after the Mustard procedure and this is presumably also the case during the stresses which may be associated with trauma, anaesthesia and surgery. The presence of complex ventricular arrhythmias was the first predictor of failure of the ejection fraction to increase with exercise.[84] Tachyarrhythmias may cause impairment of ventricular function with exercise in those patients in whom the right (systemic) ventricle is not able to increase stroke volume and cardiac output. Inadequate cardiac output during exercise may then result in sudden death.

Obstruction to venous inflow to both atria has been reported after both procedures[42,47,116] but appears to be more common after the Mustard procedure. Depressed right (systemic) ventricular function has been observed in 50% of survivors at late follow-up[52,55] and it appears that systemic ventricular function declines with time in these patients. Subjects reached 80% of predicted maximum exercise tolerance. Factors contributing to this failure are systemic levels of preload and afterload, tricuspid regurgitation and atrial dysfunction secondary to surgery which is more common after the Mustard procedure.[55,127] Diagnosis and appropriate treatment of diminished right (systemic) ventricular function and baffle-associated problems are important in patients who have undergone these procedures.

### *Arterial switch procedure*

The arterial switch operation[61] in which the aorta is connected to the left ventricular outflow tract and the pulmonary artery to the right ventricular outflow tract has now largely replaced the atrial switch in appropriate patients. This procedure requires re-implantation of the coronary arteries from the pulmonary artery to the root of the aorta and leaves the pulmonary valve as the valve for the systemic circulation. It has clear advantages in that normal physiology is restored and atrial surgery other than closure of an atrial septal defect or septostomy is avoided. Short- and medium-term results are good and there is a low incidence of significant rhythm disturbances, although there is a 20–30% incidence of supraventricular and ventricular ectopics.[97] The long-term effects of supravalvular stenosis of the great arteries, obstruction at the level of the re-implanted coronary arteries and the function of the pulmonary valve in the systemic circulation are unknown.

At 10-yr follow-up of a cohort of 444 subjects who had undergone the arterial switch operation, left ventricular size, left ventricular mass, cardiac index, filling pressures, functional status and contractility were normal, with no evidence of time-related functional deterioration. There was a 30% incidence of regurgitation through the neo-aortic valve.[26] Other series have reported normal left ventricular mass,[41] left ventricular volume, ejection fraction and stress velocity index[14,41,88,128] after the arterial switch procedure. Neo-aortic regurgitation is usually mild but more severe in the presence of previous pulmonary artery banding. Causes include intolerance of systemic pressures by the valve, damage to the valve mechanism by coronary artery re-implantation and the circumferential suture line and damage to the valve by a prior pulmonary band. Anaesthesia should maintain a mild tachycardia and encourage vasodilatation. A period of pulmonary artery banding before definitive surgery represents a higher risk of subsequent myocardial impairment with depressed contractility,[14] abnormal regional wall motion,[119] myocardial perfusion abnormalities,[118] reduced ejection fraction,[8] insufficiency of the neo-aortic valve[128] and increased left ventricular volumes.[73]

## COARCTATION OF THE AORTA

The area of coarctation is characteristically located immediately beyond the origin of the left subclavian artery, at or just distal to insertion of the ligamentum arteriosum. A coarctation may also take the form of a diffusely narrowed aortic segment that begins distal to the innominate artery and ends at a localized constriction just beyond the left subclavian artery. The basic anatomical abnormality in coarctation of the aorta is a localized deformity of the media manifested by an infolding that concentrically narrows the aortic lumen. There is a 20–40% incidence of bicuspid aortic valve associated with coarctation. In the absence of surgical correction, more than 90% of patients with coarctation die before 50 yr of age from cardiovascular and cerebrovascular disease.[119] The longest follow-up of survivors after operation shows a probability of survival of more than 70% at 40 yr after surgery.[17] Treatment is by surgical resection with either end-to-end anastomosis or widening of the coarctation with a flap of the proximal left subclavian artery.

In patients who have undergone surgical repair of coarctation there is a high incidence at follow-up of hypertension, premature coronary artery disease, re-coarctation and aortic valve disease. Despite the early success of coarctation repair there is an ongoing increased risk of premature death in these patients. The majority of the excess mortality is caused by ischaemic heart disease and stroke.

Hypertension occurs in 12–66% of patients after repair[25 93] and the incidence appears to increase with the duration of long-term follow-up.[93] The occurrence of hypertension is related partly to age at repair, with more late problems seen after repair in adolescents and adults than after repair in infants.[11 13 23 25 70] Operation between 2 and 9 yr of age on an isolated coarctation usually reduces the resting arterial pressure to normal.[70] Hypertension contributes to the excess of deaths in this group from cardiovascular disease and cerebrovascular accidents. This excess mortality is seen even in subjects with normal arterial pressure when measured intermittently at rest. The excess mortality in these patients may result from hypertension which occurs during normal activities and exercise and which has been demonstrated using ambulatory arterial pressure monitoring.[74 89] The whole of the aortic arch is abnormal in coarctation and this abnormality persists after repair. In patients who have undergone repair, microscopy of aortic arch tissue shows narrowing of the arch, increased collagen and decreased smooth muscle which lead to increased rigidity and decreased pharmacological responsiveness.[108] These structural anomalies of the aorta which persist after repair probably contribute to the post-repair hypertension seen in these patients.[89] Adaptations of the paediatric left ventricle to increased afterload caused by a coarctation include increased ventricular mass, enhanced systolic function and subnormal left ventricular wall stress.[36] These changes persist after repair even in subjects without persisting gradients or resting hypertension and abnormal left ventricular systolic and diastolic function and increased ventricular mass are found even in normotensive patients long after successful coarctation repair.[68 74 82 89] Increased ventricular mass may cause rhythm disturbances or an imbalance between myocardial oxygen supply and demand. These changes may be accelerated by normal aging.

However, repair at a young age is associated with a higher likelihood of re-coarctation[17 34 107] which ranges in incidence from 8 to 44%. Young age at repair (less than 2 yr) and low weight are independent risk factors for re-coarctation. Re-coarctation occurs in up to 40% of survivors at 16 yr[67] and an increasing incidence of this complication is expected during long- term follow-up. This complication is related to incomplete resection of the lesion (residual coarctation), failure of growth at the anastomotic site (recurrent coarctation) or to a combination of the two. The technique of surgical repair is likely to influence the occurrence of re-coarctation as a consequence of incomplete resection of ductal tissue,[130] inadequate growth of the anastomosis, fibrosis and thrombosis. The technique of subclavian flap aortoplasty is considered to be associated with lower rates of re-coarctation than resection and end-to-end anastomosis[11 107] because it avoids the need for a circumferential aortic anastomosis which fails to grow adequately. The sacrifice of the left subclavian artery which this technique entails results in diminished pulses, minimal shortening and often claudication during exercise in the left arm.[114]

Significant aortic valve disease (pressure gradient or valvular insufficiency) occurred in 37% of subjects repaired in childhood and in 58% repaired as adults[11] and results in requirement for aortic valve replacement in a significant fraction of these survivors. In several series patients have died from aortic valve disease or from the complications of aortic valve replacement. Long-term follow-up over 25–44 yr of patients who underwent coarctation repair shows that age at operation of 1–2 yr is associated with the best balance of risk for re-coarctation (less than 3%), hypertension and premature death.[17]

### CAVO–PULMONARY ANASTOMOSES

The conditions of tricuspid atresia or univentricular double inlet ventricle are characterized by the absence or hypoplasia of one of the ventricular chambers which makes an anatomical biventricular repair impossible. The disadvantages of the series circulation which these conditions produce are poor oxygenation and impaired myocardial function because of the obligatory diastolic volume load which is borne by a ventricle which is simultaneously supplying both the systemic and pulmonary circulations. A univentricular circulation is inherently inefficient because of recirculation of systemic and pulmonary venous return. As a consequence of the decrease in pulmonary resistance with time, the proportion of the entire cardiac output passing through the lungs is likely to increase and present an increasing volume load to the ventricle with no increase in systemic oxygen delivery and a decline in myocardial function. The ventricle is then situated on an unfavourable part of the Frank–Starling curve and there is progressive ventricular dysfunction. Hypoxaemia, polycythaemia and increased blood viscosity also occur.

These patients usually undergo procedures which direct systemic venous blood to the pulmonary circulation without passage through a right ventricle. The surgical options for doing this are a superior vena cava–pulmonary artery anastomosis (Glenn-type procedure), a right atrium–pulmonary artery anastomosis (Fontan procedure) or a total pulmonary–caval connection. These various procedures separate the pulmonary and systemic circulations, eliminate pulmonary recirculation and direct systemic venous return to the pulmonary artery ensuring that only systemic venous blood passes through the lungs. In these arrangements flow of blood from the systemic venous system to the left atrium occurs entirely as a result of the pressure gradient between the vena cavae and the left atrium.

For this to succeed there must be a normal or low pulmonary vascular resistance and completely normal left ventricular filling pressures at rest and during exercise. Criteria for success include a low pulmonary vascular resistance and low pulmonary artery and left atrial pressures. In patients who meet these criteria the early mortality from the procedure should be less than 5%.

### *Glenn shunt*

The original cavo–pulmonary shunt was the Glenn shunt which involved anastomosis of the superior vena cava to the right pulmonary artery and provided perfusion of only the right lung. This has been largely superceded by the bi-directional Glenn shunt in which the superior vena cava is anastomosed to the main pulmonary artery to allow perfusion of both lungs. These procedures divert only superior vena caval blood to the pulmonary circulation and inferior vena cava blood continues to shunt from right to left within the heart and to contribute to subsequent hypoxaemia and significant limitation of exercise capacity. These operations are most often used as a staging procedure to a complete Fontan procedure but may be the definitive operation in children with anatomy which is unfavourable for a Fontan procedure.

The Glenn-type procedures are associated with persisting moderate hypoxaemia because of the persistent right-to-left shunting of inferior vena cava blood. The degree of palliation provided by these shunts is generally seen to diminish after 5–15 yr resulting in progressive hypoxaemia[33 71 72 90] with increasing numbers (over 40%) of patients requiring further palliation such as a definitive Fontan procedure or construction of a peripheral arteriovenous fistula. This is one of the reasons why a definitive Fontan procedure is now performed whenever possible. Reasons for this deterioration include decreased flow to the contralateral lung in the classical Glenn shunt and the development of significant superior vena cava–inferior vena cava communications. This may be a result of progressive development of systemic venous collateral vessels which decompress the superior vena cava system into the inferior vena cava system. These vessels can often be obliterated successfully by coil embolization. Pulmonary arteriovenous shunts also develop in 10% of patients[71] and these are not always amenable to embolization. The prevalence of these shunts appears to increase with time and the reason for their formation is unclear but may be caused by increased perfusion and pressure in the lower lung fields where these fistulae occur.[24 72] There is progressive hypoxia in these patients with its attendant problems of reduced exercise tolerance, polycythaemia and thrombosis.

### *Fontan circulation*

The original Fontan procedure involved anastomosis of the right atrium to the pulmonary artery with interposition of a homograft valve.[44] This was later modified so that the right atrium and pulmonary artery were connected by direct anastomosis of the right atrial appendage to the main pulmonary artery so avoiding the use of prosthetic material. Blood from the inferior vena cava is also directed to the pulmonary circulation after this procedure.

In appropriate patients the short- and medium-term results of these procedures are good. A complete Fontan procedure often results in an arterial oxygen saturation of approximately 95%. The price paid for this is high central venous pressures and high venous pressures in the hepatic, mesenteric and renal vascular beds. Late problems with the Fontan procedure largely result from chronic increases in right atrial, central venous and abdominal venous pressures. Peripheral oedema is common and may require diuretics to limit it. There is an increasing risk of death[45] after this procedure with a 10-yr survival in large series of 60%. Problems include a 15% incidence of protein-losing enteropathy and hypoproteinaemia at 10 yr, hepatomegaly, ascites and cirrhosis.[38] Pulmonary arteriovenous fistulae may also develop after the Fontan procedure in the same way as after the Glenn procedure.[24] Longer follow-up is necessary to determine if this becomes a common complication of the Fontan procedure. Supraventricular tachycardias have been reported with a 20-40% incidence between 5 and 15 yr after operation[38] and more than 40% of patients have rhythm abnormalities on 24-h ambulatory ECG at 10 yr,[29 121] including abnormal sinus node function, prolonged refractory condition of the atrium, delayed intra-atrial conduction, inducible atrial arrhythmias and the bradycardia– tachycardia syndrome. The risk of arrhythmias increases with the duration of follow-up, and life-long surveillance for these patients is required to determine the need for pharmacological therapy or pacemaker insertion. These patients have limited ability to increase cardiac output during exercise or stress. Cardiac index at rest and during exercise is low compared with controls and exercise may produce functional conduit obstruction in asymptomatic subjects.[48 86 104 105] Ventilation–perfusion abnormalities are common.

Other significant problems include thrombosis[35] and stroke.[38] Factors which may predispose to thrombus formation include low cardiac output (particularly if there are areas within the heart prone to stasis such as the pulmonary artery stump or an enlarged redundant right atrium), supraventricular arrhythmias such as atrial flutter and fibrillation, the use of synthetic material or anastomotic stenosis. There are abnormalities of the haemostatic mechanism predisposing to thrombosis in more than 60% of patients who have undergone a Fontan procedure.[28] The commonest of these is protein C deficiency. A review of cerebrovascular accidents after the Fontan procedure found a 2.6% incidence of stroke among 645 patients. Seven of sixteen patients were found to have intracardiac thrombus which in every case was in a position to generate systemic emboli.[39] Currently there are no well founded guidelines on the place of routine anticoagulation in these patients. Some institutions anticoagulate patients perceived as being at high risk of thrombotic complications.

The morbidity and mortality of a Fontan procedure in patients with a single ventricle may be reduced if staged procedures are performed with an intermediate stage of a bidirectional Glenn shunt being included. Each stage, however, exposes the sinoatrial node to the risk of injury and there is an increased incidence of sinoatrial node dysfunction in patients who have undergone staged procedures (16%) rather than a single Fontan procedure (8%).[78]

### *Total cavo–pulmonary connection*

A total cavo–pulmonary connection involves anastomosis of the superior vena cava directly to the right pulmonary artery and the construction of an intra-atrial conduit to direct inferior vena cava blood to the main pulmonary artery.[31] This innovation was introduced after the demonstration that the right atrium made an insignificant contribution by pumping to venous return in a valveless Fontan atriopulmonary connection and that inclusion of the whole right atrium in this circulation may be detrimental. The procedure was intended to reduce the amount of right atrial dissection required and consequent damage to the sinoatrial node, reduce volume distension of the right atrium, reduce turbulence in venous blood flow, possibly reduce the incidence of postoperative arrhythmias and reduce the incidence of right atrial thrombosis.

After these various procedures success depends on maintaining low values for pulmonary vascular resistance and left atrial pressure. Left atrial pressure reflects the diastolic properties of the ventricle and the function of the systemic atrioventricular valve. Factors which impede pulmonary blood flow include increased left ventricular end-diastolic pressure, atrioventricular valve stenosis or regurgitation, loss of sinus rhythm with cannon waves which increase left atrial pressure, pulmonary vein stenosis, increased pulmonary microvascular resistance, obstructed or stenotic pulmonary arteries or cavo–pulmonary anastomotic narrowing. These patients are very sensitive to changes in pulmonary vascular resistance and have a very limited ability to compensate for changes in this. After a cavo–pulmonary anastomosis an increase in pulmonary vascular resistance is manifested as a decrease in cardiac output and peripheral perfusion because of limited return to the systemic ventricle. Factors which may cause or contribute to an increase in pulmonary vascular resistance include hypoxaemia, hypercapnia, acidosis, excessive airway pressure, positive end-expiratory pressure and extrinsic pulmonary compression by pneumothorax or effusion. Central venous pressure must be maintained and manoeuvres which increase intrathoracic pressure such as intermittent positive pressure ventilation and positive end-expiratory pressure should be used cautiously. Any reduction in myocardial performance or loss of sinus rhythm are likely to be poorly tolerated. These patients should be considered to be at high risk of thrombotic complications and some antithrombotic regimen must be considered in all patients undergoing anaesthesia and surgery.

### ATRIOVENTRICULAR SEPTAL DEFECT

Atrioventricular canal septal defects are of two types. The partial defect or ostium primum results from failure of the septum primum to fuse with the endocardial cushions. This is usually associated with a cleft in the anterior leaflet of the mitral valve. There is left-to-right shunting at the atrial level, some degree of mitral regurgitation, development of increasing degrees of atrioventricular block and a significant risk of endocarditis on the cleft mitral valve. This lesion is usually repaired in infancy which involves closure of the defect and repair of the mitral valve. Results are very good although long-term sequelae may include residual pulmonary hypertension, persistent mitral regurgitation and atrioventricular block.

Complete atrioventricular septal defect results from failure of fusion of the septum primum with the endocardial cushions, failure of the endocardial cushions to fuse and a deficiency in the membranous portion of the ventricular septum. There is a common single atrioventricular valve rather than discrete tricuspid and mitral valves. This lesion usually results in what is effectively a univentricular heart. There is systemic pressure in both ventricles and early onset of pulmonary hypertension and heart failure. There is also the development of progressive degrees of atrioventricular conduction block and a high risk of endocarditis on the valve. Survival beyond childhood is unusual without corrective surgery unless there is pulmonary stenosis which protects the pulmonary circulation. Significant pulmonary vascular changes develop early in life but are said to be reversible if definitive surgery is carried out before 2 yr of age. Traditional management has consisted of a pulmonary artery band in the neonatal period to protect the pulmonary circulation from systemic pressures and high flows and definitive repair 2–3 yr later. In recent years definitive repair has been performed in the first year of life to minimize the long-term sequelae of a large left-to-right shunt and mitral regurgitation. Definitive surgery involves repair of the atrial and septal defects with patches of Goretex or Dacron and repair and resuspension of the left atrioventricular valve to restore competence. Surgical closure is associated with a risk of damage to the atrioventricular node and the bundle of His. In the early postoperative period transient complete atrioventricular block is common. Atrioventricular conduction block persists in 5% of patients and may appear late after repair in 2%. If the left atrioventricular valve is unrepairable a prosthesis is required. Atrial flutter or fibrillation occurs late in 5–10% of patients.

Long-term effects depend on residual conduction block, the degree of pre-existing pulmonary vascular disease and pulmonary hypertension, and left ventricular function. A common problem after repair is progressive left atrioventricular valve regurgitation which generally occurs because of separation of the two repaired components of the reconstructed septal leaflet of the valve. Subaortic stenosis may develop late after repair because of turbulence produced by the abnormal attachment of the left atrioventricular valve resulting in the formation of a discrete fibrous shelf which may need to be excised.

## RIGHT VENTRICLE–PULMONARY ARTERY CONDUITS

In the case of a lesion involving irreparable right ventricular outflow tract obstruction, an initial shunt procedure is performed to ensure pulmonary perfusion and subsequently followed by placement of an extracardiac valved conduit from the right ventricle to the pulmonary circulation to bypass the obstruction.[40 101] Relevant lesions include the tetralogy of Fallot with pulmonary atresia, truncus arteriosus and pulmonary atresia. Conduits used have included synthetic woven Dacron tubular conduits containing porcine aortic valves, valved aortic homografts and valved pulmonary homografts.

The commonest complication is obstruction which can result from stenosis at the distal anastomosis with the pulmonary vascular tree, compression of the ventricular end of the conduit during systole, accumulation of thrombotic and fibrous material on the wall of the conduit, compression of the conduit by the sternum and calcific or thrombotic stenosis of the valve. Other complications include regurgitation through an incompetent valve with an increased volume load and the possibility of high output heart failure. A loud murmur is almost universal from the conduit and should not be taken as evidence of stenosis or regurgitation. A feature of these conduits is that remarkably high gradients may exist across them in the absence of symptoms, and serial cardiac catheterization has been advocated as a method of surveillance.[3] Common symptoms of conduit failure include limitation of exercise tolerance, fatigue, dyspnoea and dizziness. Signs include increasing intensity of murmurs, heart failure and cyanosis.

The early use of porcine-valved Dacron conduits was associated with a high incidence of operative complications and early conduit failure resulting from graft rigidity or large size relative to the recipient. Late failures were caused by valve degeneration resulting in valvular stenosis and incompetence. Mechanisms of conduit failure as a result of valvular stenosis include thrombosis, commissural fusion and calcification. Valvular incompetence is caused by tears, fusion of cusps to the conduit wall and endocarditis. A particular problem is the accumulation of a pseudo-epithelium or peel which does not adhere to the tightly woven artificial material and lifts away to obstruct the conduit.[3] There is a high reoperation rate which was as high as 100% in one series.[63] With the growth of organ transplantation and expertise in harvesting organs and tissue preservation, human aortic and pulmonary homografts became available and artificial conduits were abandoned in favour of these natural conduits.

Initially, valved aortic allografts were used which have a lower early failure rate than artificial conduits but are also associated with operative complications, severe early calcification, late conduit obstruction[9 76 81] and valvular stenosis or regurgitation (60% at a mean follow-up of 3.4 yr).[5] Cryopreserved pulmonary allografts have several features which make them superior to aortic homografts for right ventricular outflow tract reconstruction. They are bifurcated and can be incorporated into repair of pulmonary artery stenoses. They also have a tissue consistency similar to that of the recipient pulmonary arteries. Anticoagulation is not necessary and they have better valvular mechanics than aortic allografts.[5] Pulmonary artery homografts have been shown to be more durable and to calcify to a lesser extent than aortic homografts.[9] Pulmonary artery homografts are now the conduit of choice for reconstruction of the right ventricular outflow tract.

## PREGNANCY

Increasing numbers of women with treated congenital heart disease are reaching reproductive age and anaesthetic management during labour and delivery is needed. Ideally there should be an opportunity for anaesthetic assessment of the patient early in pregnancy in the light of a recent cardiological review and regular assessments during pregnancy to avoid the potential situation of being confronted at short notice with a complex, high-risk parturient in labour. Management is based on knowledge of the normal physiological changes which occur during pregnancy, existing degree of cardiovascular impairment, associated pathophysiology and anticipated effects of analgesic and anaesthetic techniques. Features of interest are the existing anatomy, presence and magnitude of intracardiac shunts, degree of functional impairment, ability to exercise, ventricular failure, hypoxaemia and arrhythmias. The presence and severity of pulmonary hypertension is particularly important as the risk of maternal mortality approaches 30% with each pregnancy if there is significant pulmonary vascular disease.[92] Functional deterioration during pregnancy is likely in more than 50% of women with cyanotic heart disease compared with 15% of those with acyanotic disease.[111] Functional deterioration is also more likely in the presence of congestive cardiac failure than in its absence (30% *vs* 5%). Maternal congenital heart disease which results in residual hypoxaemia is associated with poor fetal growth, a high rate of spontaneous abortion, premature labour and a significant incidence of fetal complications. The risk to the fetus is broadly in proportion to the degree of maternal hypoxaemia with a 50% risk of fetal death if the maternal arterial oxygen saturation is less than 85% or the packed cell volume is more than 65%.[94] Neonates tend to be smaller than average with a high perinatal mortality. There is also the risk of congenital heart disease in the fetus as, although most patients do not have a recognizable genetic condition, there is a genetic component to the development of much congenital heart disease. The recurrence risk of congenital heart disease in a sibling of an index case is 1–8%.[7] As more women survive pregnancy accumulating data suggest that the risk in the offspring of an index case is higher, especially if the mother rather than the father is affected.[125]

Women with a surgically closed atrial septal defect, ventricular septal defect or patent ductus arteriosus without residual pulmonary hypertension and who are asymptomatic can expect to labour in an essentially normal manner,[111] as may patients with corrected tetralogy of Fallot without residual pulmonary stenosis or arrhythmias.[112] The haemodynamic stress imposed by pregnancy tends to be tolerated badly in the presence of stenotic lesions and low or fixed cardiac output states including the Fontan circulation. Failure of a morphological right ventricle acting as a systemic ventricle such as after the Mustard or Senning procedures for transposition of the great arteries may be seen.[77] In the presence of good myocardial function or regurgitant lesions, pregnancy is generally better tolerated.

In high-risk parturients, the objectives during analgesia and anaesthesia, if required, should be to preserve ventricular function, maintain adequate preload, avoid anaesthetic-induced myocardial depression and to prevent undesirable changes in the direction or magnitude of intracardiac shunts. In general vaginal delivery is the aim with Caesarean section reserved for obstetric indications. If fluctuations in arterial pressure and cardiac output associated with labour are particularly undesirable and may not be controlled, Caesarean section is indicated. Although in many high-risk patients there are theoretical reasons to avoid decreases in systemic vascular resistance or preload, especially if there is a right-to-left shunt in the presence of pulmonary hypertension (where increases in the shunt worsen hypoxaemia) or ventricular hypertrophy, extradural analgesia has been used in many such patients. When extradural block is produced slowly and incrementally with appropriate fluid loading and vasopressor use, hypotension can be minimized while the excellent analgesia it provides minimizes rapid fluctuations in preload, cardiac output and heart rate.[43 62 77 109] Voluntary pushing during the second stage of labour is minimized to avoid excessive Valsalva effects and delivery may be facilitated by forceps. Extradural or subarachnoid opioids have been used successfully to provide analgesia in high-risk cases.[2 4] This technique reduces the requirement for local anaesthetic administration and minimizes disturbances in maternal haemodynamics associated with vasodilatation and the reduction in preload, although the use of opioids alone is inadequate for operative delivery. Defective haemostasis is associated with anticoagulation, pulmonary hypertension and polycythaemia and should be considered before central regional blocks are performed. When general anaesthesia is used in high-risk patients the technique should be modified to avoid the risk of hypotension associated with a traditional rapid sequence induction.

## Conclusion

As the care of children with congenital heart disease continues to evolve, the spectrum of late complications associated with treatment is likely to change. The trend of performing early and definitive surgery whenever possible should improve the prognosis of several conditions and reduce the incidence of late complications. Newer techniques such as the arterial switch for transposition are expected to largely eliminate the late complications of atrial switch procedures. The use of cardiac catheterization techniques to close atrial septal defects and patent ductus arteriosus reduces the early morbidity and may further improve the good long-term outcome of these conditions.

SHORT COMMUNICATIONS

# Wound infiltration with local anaesthetic after abdominal hysterectomy

T. F. COBBY AND M. F. REID

**Summary**

The study was performed to investigate if wound infiltration with 20 ml of 0.5% bupivacaine after abdominal hysterectomy improved analgesia and reduced morphine requirements from a patient-controlled analgesia system during the first 6 h after operation. Forty patients undergoing abdominal hysterectomy were allocated randomly to one of two groups. The study was performed in a double-blind controlled manner. Morphine requirements in the first 6 h after operation were similar in both the control (30.3 mg) and bupivacaine (29.0 mg) groups. Cumulative hourly morphine requirements did not differ significantly between the two groups. Pain scores assessed by visual analogue were similar in both groups. (*Br. J. Anaesth.* 1997; **78**: 431–432).

**Key words**

Pain, postoperative. Anaesthetics local, bupivacaine. Surgery, gynaecological

Beneficial effects of subcutaneous and intrafascial infiltration with local anaesthetic have been demonstrated for inguinal hernia repair and cholecystectomy, with reduced postoperative pain and opioid requirements.[1 2] However, little work has been performed on lower abdominal operations. A study of subcutaneous infiltration of local anaesthetic of the wound edges after lower segment Caesarean section demonstrated some reduction in morphine consumption but only on a weight-adjusted basis.[3]

The purpose of this study was to see if subcutaneous infiltration of bupivacaine after abdominal hysterectomy reduced morphine requirements after operation. Analgesia was assessed by pain scores, and opioid consumption was recorded using a patient-controlled analgesia (PCA ) system.

## Methods and results

After obtaining Ethics Committee approval, we studied 40 ASA I–II patients, aged 20–60 yr, weighing 40–100 kg; patients were undergoing elective abdominal hysterectomy and gave written informed consent to the study, which was performed in a prospective, double-blind, randomized manner.

Each patient was visited before operation and instructed on the use of the PCA machine. The use of a standard 100-mm visual analogue scale (VAS) for scoring pain was explained to the patient at this time. Patients were excluded if they had known allergy to bupivacaine, were concurrently using either opioids or non-steroidal anti-inflammatory drugs or were unable to use the PCA apparatus.

All patients received a standard anaesthetic. Anaesthesia was induced with fentanyl 3.0 $\mu$g kg$^{-1}$ and propofol 2–3 mg kg$^{-1}$. Atracurium 0.5 mg kg$^{-1}$ was administered to facilitate tracheal intubation and for neuromuscular block during the procedure. Anaesthesia was maintained with 1% isoflurane and 70% nitrous oxide in oxygen. Additional fentanyl and atracurium were used as required. Cyclizine 50 mg was given i.v. 20 min before the end of the operation as an antiemetic. Before antagonism of residual neuromuscular block with neostigmine 2.5 mg and glycopyrronium 0.5 mg, each patient was allocated randomly to one of two groups to receive either 20 ml of 0.5% bupivacaine by subcutaneous infiltration (to a maximum of 0.4 ml kg$^{-1}$) by the surgeon or no infiltration. In the recovery room, recovery staff administered i.v. morphine as postoperative analgesia as necessary, according to standard hospital procedures.

Patients then received additional analgesia by PCA with morphine 1 mg ml$^{-1}$, using a 1-ml bolus and a 5-min lockout, and additional antiemetic as required.

Pain was assessed hourly for the first 6 h after operation using a standard 100-mm VAS.

Differences in opioid requirements between the groups were assessed using an unpaired Student's $t$ test. Pain scores were compared using a Mann–Whitney $U$ test. $P<0.05$ was considered statistically significant.

Power analysis performed before the study indicated that 20 patients in each group would be required to detect a reduction in morphine use of 25% at 6 h, with a power of 0.8.

The groups were similar in characteristics. Mean doses of fentanyl given during operation were 234.7 (SD 67) $\mu$g and 240 (71.2) $\mu$g in the control and infiltration groups, respectively. Morphine requirements

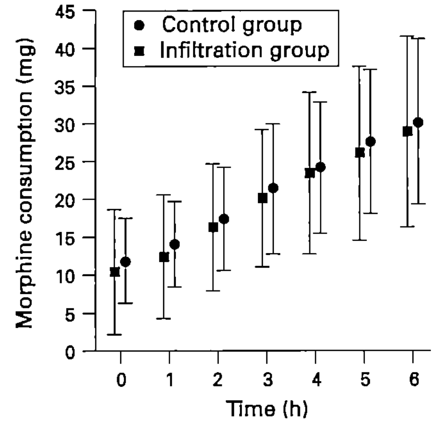

*Figure 1* Cumulative hourly morphine requirements (mean, SD) in the control and infiltration groups. The two groups have been separated for clarity.

were 11.8 (5.4) mg for the control group and 10.4 (8.2) mg for the infiltration group in the recovery area (time 0, fig. 1). At 6 h after operation, total morphine requirements were 30.3 (10.9) mg and 29.0 (12.5) mg, respectively. Similarly, cumulative hourly morphine requirements did not differ (Student unpaired *t* test) (fig. 1).

Pain scores on bending the knees and at rest during the first 6 h after operation were similar in both groups (Mann–Whitney *U* test).

## Comment

We have found that subcutaneous wound infiltration with 0.5% bupivacaine had no analgesic sparing effect after abdominal hysterectomy. Indeed, morphine consumption for the first 6 h was almost identical in the two groups (fig. 1). We may have failed to find a difference between the two groups because of the marked variability in individual opioid requirements. There was also a large variation in pain scores, despite the use of PCA. This, together with individual pharmacokinetic and pharmacodynamic handling of morphine, add to the variability in morphine consumption and may make it more difficult to demonstrate a morphine sparing effect of wound infiltration.

There were no differences in pain scores at rest or on movement. For a difference to be caused by wound infiltration with bupivacaine, a difference before 6 h would be expected. The 1-h pain scores in the control group were anomalous in that median pain scores were higher at rest than on movement, possibly because the women were still drowsy from their anaesthetic, but may indicate some unreliability of visual analogue pain scoring. However, Sinclair and colleagues[4] demonstrated a reduction in doses of i.m. buprenorphine and reduced mean visual analogue pain scores at rest in the first 24 h after application of lignocaine spray to the wound following closure of the muscular fascia after abdominal hysterectomy. They found the greatest improvement in pain scores in the first 6 h after operation.

Wound infiltration has been demonstrated to have an analgesic sparing effect after herniotomy[1] and provide similar analgesia to that of ilioinguinal nerve block for herniotomies in children.[5] There is conflicting evidence from previous studies as to the benefit of wound infiltration with local anaesthetics after intra-abdominal surgery. Trotter and colleagues[3] demonstrated no analgesic sparing effect after Caesarean section with wound infiltration. Other studies have found wound infiltration to be effective in reducing opioid demand and improving pain scores after Caesarean section and to be comparable with bilateral ilioinguinal nerve block.[6] These conflicting results may have been because the use of the term "wound infiltration" can encompass either subcutaneous or all layers of the incision. Studies have shown that by infiltrating all layers of the abdominal wall, opioid administration can be reduced after open cholecystectomy.[2]

# Induction characteristics of 2% propofol in children

A. BORGEAT, T. FUCHS AND E. TASSONYI

## Summary

We have conducted a prospective, randomized study to evaluate the characteristics of induction of anaesthesia in children with 2% propofol. Children were allocated to receive propofol 3 mg $kg^{-1}$ (group A), 4 mg $kg^{-1}$ (group B) or 5 mg $kg^{-1}$ (group C) of the 2% formulation. We observed a high incidence of spontaneous movements (90%) in group A and an incidence of coughing of 70% in group C. Induction in group B was characterized by a short induction time, low incidence of spontaneous movements (20%), pain on injection (10%) and excellent conditions for manual ventilation. (*Br. J. Anaesth.* 1997; **78:** 433–435).

**Key words**
Anaesthetics i.v., propofol. Anaesthetic techniques, induction. Formulations, propofol. Children.

Propofol 1% is an i.v. anaesthetic agent which is now used routinely in paediatric anaesthesia.[1] Spontaneous movement is one of the side effects observed during induction of anaesthesia with 1% propofol.[2] It was demonstrated that increasing the loading dose from 3 to 5 mg $kg^{-1}$ resulted in a significant decrease in these movements.[2] However, the volume needed to be administered may be quite large and the required time to infuse such a volume through a 22-gauge or smaller catheter may be prolonged. It has been shown that slow injection is associated with more frequent and intense pain on injection,[3] an especially troublesome side effect in children.

A new formulation containing 2% propofol has been prepared recently; this reduces by half the volume and fat load. The 2% solution was prepared mainly for intensive care sedation, but the use of smaller volumes may be advantageous in children. We undertook this study to evaluate and assess the clinical tolerance and quality of induction of anaesthesia in children with this new formulation.

## Methods and results

After obtaining parental informed consent and institutional Ethics Committee approval, we studied 45 ASA I children, aged 5–12 yr. All children were undergoing elective ear, nose and throat (ENT) procedures of short duration. Exclusion criteria were known allergy to propofol or lignocaine, mental disorders or a previous problem with general anaesthesia.

EMLA emulsion cream (lignocaine 25 mg $g^{-1}$ and prilocaine 25 mg $g^{-1}$) was applied to the dorsum of both hands and covered with an impervious dressing approximately 1 h before operation. No sedatives were given before induction of anaesthesia. On arrival in the anaesthetic room, heart rate and arterial pressure were recorded with an automatic device (Cardiocap, Datex, Helsinki). Other monitors included a pulse oximeter (Cardiocap, Datex, Helsinki) and a precordial stethoscope. A 22-gauge catheter was inserted into a vein on the dorsum of the hand. Children were allocated prospectively to group A (2% propofol 5 mg $kg^{-1}$), group B (2% propofol 4 mg $kg^{-1}$) or group C (2% propofol 3 mg $kg^{-1}$) according to a computer randomized table. Propofol was premixed with lignocaine in a ratio of 10:1 (10 mg of propofol for 1 mg of lignocaine).

Children's lungs were preoxygenated for 1 min with oxygen ($F\text{I}_{\text{O}_2}$ 1.0). The induction bolus was given within 5–10 s. Two minutes later continuous infusion of propofol 0.2 mg $kg^{-1}$ $min^{-1}$ was started via an automatic pump (IVAC 711, San Diego, CA, USA). At this time children received alfentanil 20 mg $kg^{-1}$ and vecuronium 0.1 mg $kg^{-1}$.

A nurse was responsible for preparing and administering the propofol injection. At the end of the induction bolus, an independent investigator, unaware of the child's group assignment, observed and communicated with the child during induction and assessed the presence of pain on injection according to the following scale: (a) verbal complaints without withdrawal of the arm, (b) withdrawal of the arm with or without verbal complaints. The appearance of spontaneous movements was assessed according to the following classification: (a) movements of the hand and fingers, (b) movements of the arm, (c) movements of the arm and shoulder. Other variables assessed were induction time, defined as the time between end of propofol administration and loss of the eyelash reflex, arterial pressure and heart rate changes, erythema or cutaneous rash and cough/hiccup. Ease of ventilation of the lungs was assessed as excellent, smooth or unsatisfactory.

*Table 1* Characteristics of induction with 2% propofol 4 mg kg$^{-1}$ (mean (SD or range) or number)

| Patient data | |
|---|---|
| *n* | 50 |
| Age (yr) | 8 (5–12) |
| Weight (kg) | 23 (8) |
| Sex (M/F) | 33/17 |
| Induction characteristics | |
| *n* | 50 |
| Induction time (s) | 12 (3) |
| Pain | |
| (a) | 5% |
| (b) | 5% |
| Spontaneous movements | |
| (a) | 15% |
| (b) | 5% |
| Erythema | 6% |
| Cough | 0% |
| Hiccup | 4% |
| Ease of ventilation | |
| 1 | 88% |
| 2 | 12% |
| 3 | 0% |

At the end of the study it was decided to add another 35 children to the group which showed the best clinical tolerance.

Patient characteristics were similar in the three groups. All groups were comparable in induction times, incidence of pain on injection and appearance of a rash or erythema.

A high incidence of spontaneous movements (90%) was observed in the 3-mg kg$^{-1}$ group which resulted in poor induction. In the 5-mg kg$^{-1}$ group, a high incidence of coughing (70%) was noted which rendered the management of ventilation unpleasant. In contrast, the 4-mg kg$^{-1}$ dose produced a rapid and smooth induction with few side effects (table 1).

Haemodynamic changes were comparable in all three groups, with a mean decrease in arterial pressure of 5–15% from basal values 1 min after injection, a decrease of 10–15%, 2 min and 15–20%, 3 min after administration of the propofol bolus. Changes in heart rate were also similar between groups, ranging from a mean decrease of 5% to an increase of 15%, 1, 2 and 3 min after induction.

## Comment

We have assessed the quality of induction of anaesthesia in children with the new formulation of 2% propofol and found that the induction dose of 3 mg kg$^{-1}$ was inadequate as we observed a high incidence of spontaneous movements. A dose of 5 mg kg$^{-1}$ was associated with a high incidence of coughing which interfered with manual ventilation. In contrast, a dose of 2% propofol 4 mg kg$^{-1}$ allowed rapid and smooth induction with few side effects. The ease of performing manual ventilation was particularly striking.

Induction time, that is interval between the end of drug administration and loss of the eyelash reflex, was 12 (3) s in the 4-mg kg$^{-1}$ group. Puttick and Rosen,[4] using the same criteria, found an induction time of 21 (3) s in children aged 2–11 yr who received 1% propofol 3.5 mg kg$^{-1}$. It is conceivable that a higher brain drug concentration is reached faster with the 2% formulation, thus explaining the very short induction time. A short induction time has advantages in young children, especially in those who have reduced pulmonary function.

One of the striking features of induction with 2% propofol 4 mg kg$^{-1}$ was the ease of performing manual ventilation. Manual ventilation was assessed as very easy and comfortable in 88% of children. Propofol 1% is also known to provide excellent intubating conditions; Pedersen[5] observed that sedation with 1% propofol in patients with hyperactive airway disease provided marked bronchodilatation.

Spontaneous movements limited to the finger and hand were observed in 15% of children and those involving the arm in 5%. The movements were, as described previously,[2] dystonic in nature. The incidence of spontaneous movements was similar to that reported by Purcell-Jones and colleagues[6] after a bolus of 1% propofol 2.5 mg kg$^{-1}$. The appearance of these movements decreased when the initial dose of 1% propofol was increased to 5 mg kg$^{-1}$,[2] but was also reported to be high when the induction dose was 3 mg kg$^{-1}$.[2] The trend in observing more severe and frequent spontaneous movements with a lower dose of 2% propofol is similar to that observed with 1% propofol.

Pain on injection was noted in 10% of children receiving 2% propofol pre-mixed with 1% lignocaine (in a ratio of 2% propofol 10 mg : lignocaine 1 mg). Pre-mixing 1% lignocaine with 1% propofol appeared to be the most efficient means of reducing pain on injection. The incidence observed in this study was similar to the results obtained with a mixture of 1% propofol–lignocaine.[7] The more concentrated formula of 2% propofol does not appear to increase the incidence of pain on injection when pre-mixed with lignocaine.

Other excitatory events such as cough and hiccup were rare in the 4-mg kg$^{-1}$ group. These results are comparable with those observed with 1% propofol.[2] We believe that the high incidence of cough observed with 2% propofol 5 mg kg$^{-1}$ may be explained by a sudden high propofol brain concentration leading to some excitatory effects on the cough centre.

Haemodynamic changes (arterial pressure and heart rate) did not differ from values observed after induction with the 1% formulation.

We have found that the new formulation of 2% propofol, at a dose of 4 mg kg$^{-1}$, provided induction characteristics in children similar to those observed with 1% propofol in terms of haemodynamic stability, pain on injection and spontaneous movements. However, the 2% formulation had the advantage of reducing the time of injection and volume of drug, of providing a short induction time and offering excellent conditions for manual ventilation.

# A study of mixing conditions during nitric oxide administration using simultaneous fast response chemiluminescence and capnography

L. FOUBERT, K. MAREELS, M. FREDHOLM, S. LUNDIN AND O. STENQVIST

## Summary

We have evaluated the mixing properties of nitric oxide in inspired gases for five different administration techniques. Nitric oxide and carbon dioxide were delivered to the ventilator system before the ventilator or after the ventilator as a continuous flow, either directly into the inspiratory limb or into a mixing chamber positioned in the inspiratory limb. Both gases were delivered as above but synchronized with inspiration. Mixing conditions were evaluated using fast response chemiluminescence for nitric oxide and capnography for carbon dioxide analysis. Administration of nitric oxide and carbon dioxide directly into the inspiratory limb as a continuous flow or with a magnetic valve-controlled synchronized flow resulted in peak concentrations of 236% and 220%, respectively, of expected values. The use of a mixing chamber reduced these values to 104% and 102%, respectively. Administration of nitric oxide as a continuous flow into the tubing of an intermittent flow ventilator resulted in highly fluctuating inspiratory peak concentrations, which could be avoided with a mixing chamber. (*Br. J. Anaesth.* 1997; **78**: 436–438).

**Key words**
Pharmacology, nitric oxide. Gases non-anaesthetic. Equipment, delivery systems.

Inhaled nitric oxide is used for the treatment of acute lung injury, persistent pulmonary hypertension of the newborn and right ventricular failure after cardiac surgery. Safe administration demands low levels of its toxic oxidation product, nitrogen dioxide. As the formation of nitrogen dioxide is proportional not only to the square of the nitric oxide concentration, but also to the contact time between nitric oxide and oxygen,[1] administration of nitric oxide after the ventilator has been advocated to reduce contact time and hence nitrogen dioxide formation.[2] To avoid highly fluctuating concentrations, delivery of nitric oxide into the inspiratory limb only during inspiration has been suggested. This study was designed to evaluate mixing properties of nitric oxide for five different delivery techniques.

## Methods and results

A Servo 900 C ventilator (Siemens Elema, Solna, Sweden) was driven with 100% oxygen via its low pressure inlet to generate a minute volume of 9.5 litre min$^{-1}$, at 10 and 20 cycles min$^{-1}$, with inspiratory times of 25% and 33%. Nitric oxide and carbon dioxide at flow rates of 250 ml min$^{-1}$ for each gas were delivered to the breathing system by two mass flow regulators (Bronkhorst Hightech BV, Ruurlo, The Netherlands), the flows of which were checked with a precision gas flowmeter (ADH 3000, J &W Scientific, Fisons, Folsom, CA, USA). The gases were added either before the ventilator or as a continuous flow immediately after the ventilator into the inspiratory limb, or into a mixing chamber and soda lime absorber connected in series with the inspiratory limb. They were also delivered as above, but synchronized with inspiration via a magnetic valve-controlled Siemens Servo 945 Nebulizer (Siemens Elema, Solna, Sweden).

The inspiratory limb was connected to an "alveolar lung chamber" (1 litre) in which a continuous flow of air 3.5 litre min$^{-1}$ was mixed to mimic lower "end-tidal" nitric oxide/carbon dioxide concentrations. The chamber was connected to an artificial lung with a compliance of 70 ml cm$^{-1}$ $H_2O$. At the Y-piece we attached a fast response chemiluminescence (CL) analyser for nitric oxide (NOX 4000, Seres, Aix en Provence, France) with a sampling rate of 1 litre min$^{-1}$, and capnography for carbon dioxide (Ultima SV, Datex, Helsinki, Finland) with a sampling rate of 250 ml min$^{-1}$. Nitric oxide and carbon dioxide tracings were recorded on a flat bed recorder. The mixing chamber–soda lime unit comprised two 900-ml canisters of which one was filled with 450 g of soda lime (Q-sorb, Anmedic AB, Vallentuna, Sweden), exhausted for carbon dioxide before the experiments. As the primary carbon dioxide concentration was 100% and the nitric oxide concentration was 1000 parts per million (ppm) in nitrogen (AGA Gas AB, Lidingö, Sweden), the expected concentrations at the Y-piece were 2.5 % for carbon dioxide and 25 ppm for nitric oxide, if complete mixing was achieved.

When carbon dioxide was administered before the

ventilator or after the ventilator into the mixing chamber, whether as continuous or synchronized flow, final concentrations varied between 2.35% and 2.60%, with a clear plateau phase for each administration technique (table 1). For nitric oxide, this resulted in concentrations of 22–28 ppm, with only a flattened peak and no plateau phase. Continuous administration of both gases directly into the inspiratory tubing resulted in inspiratory carbon dioxide concentrations of 0.70–5.90% and nitric oxide concentrations of 15–42 ppm, both with a sharp peak at early inspiration. When administered synchronized with inspiration, concentrations varied between 0.70 and 5.50% for carbon dioxide and between 13 and 28 ppm for nitric oxide.

## Comment

Nitric oxide delivery systems should produce stable and uniformly distributed nitric oxide concentrations with minimal formation of nitrogen dioxide. A fixed inspired nitric oxide fraction can be obtained easily when nitric oxide is mixed with oxygen and air before the ventilator, using sophisticated and expensive devices such as mass flow regulators[3] or, alternatively, even simple flowmeters. This technique however is restricted to ventilators with a low pressure inlet. The gases can also be mixed at high pressure, which increases the number of usable ventilators. This technique necessitates the use of several blenders,[4] liable to oxidation by nitric oxide and nitrogen dioxide, requires rather complicated calculations when changes in nitric oxide and oxygen concentrations are necessary and may additionally increase nitrogen dioxide production as oxidation of nitric oxide is proportional to the cube of the gas pressure. Both techniques increase residence time of nitric oxide in the ventilator and are believed to enhance nitrogen dioxide formation.

Administration of nitric oxide in the inspiratory limb has been used to reduce the contact time between nitric oxide and oxygen.[2] Our experiments however showed that continuous administration of carbon dioxide and nitric oxide into the inspiratory limb of an intermittent flow ventilator resulted in fluctuating inspiratory concentrations at the Y-piece. For carbon dioxide, a peak of 236% and a minimum of 34% of the expected value was measured, whereas for nitric oxide values varied between 160 and 60%. This also shows that the fast response CL analyser cannot detect these rapid fluctuations and considerably underestimates peak and overestimates minimum concentrations. With a continuous flow, nitric oxide supplied from a concentrated cylinder (usually approximately 1000 ppm) accumulates at the entry point in the inspiratory limb during expiration and forms a nitric oxide plug. The latter moves nearly undiluted to the patient during the next inspiration. Although we have no flow data and consequently no idea of the volume of gas with the high concentration, we expect that the first part of the tidal volume would preferentially reach alveoli with a low time constant, exposing them and their bronchiolar structures to high nitric oxide concentrations. This may result not only in nitric oxide related toxicity, but also in inhomogeneous distribution of nitric oxide in the lungs. In view of our data, dose–response curves in studies where nitric oxide was delivered as a continuous flow into the inspiratory limb may have to be reconsidered, as it is not clear if nitric oxide is mixed completely with the tidal volume when entering the lungs. Furthermore, the equipment used to monitor nitric oxide and nitrogen dioxide concentrations was probably not sophisticated enough to detect these peak concentrations. Synchronizing nitric oxide flow with inspiration with a magnetic valve clearly does not solve the problem of inhomogeneous mixing. A pressure increase upstream of the synchronizing unit during expiration probably results in bolus injection as soon as it opens during inspiration, as suggested by carbon dioxide concentrations between 220 and 28% of expected values. Recently, methaemoglobin concentrations of 67% were reported in a patient receiving nitric oxide 8–45 ppm, as measured with a CL analyser.[5] Nitric oxide was delivered in the inspiratory limb with a flow synchronized to ventilator flow. Our data support the authors' speculation that the CL analyser underestimated real inspiratory peak concentrations. The latter were probably responsible for the extremely high methaemoglobin concentrations in this patient.

In our experiments a mixing chamber–soda lime canister provided effective mixing of the gases, as evidenced by a plateau phase in the carbon dioxide curves, but increased residence time of the gases in the system. Our data provide no conclusive information on nitrogen dioxide production for two reasons: soda lime was exhausted for carbon dioxide and may not have had its full capacity to scavenge nitrogen dioxide, and the CL analyser was not fast enough to detect rapid changes in nitric oxide concentrations and therefore was unable to measure corresponding nitrogen dioxide concentrations correctly, as the latter are measured indirectly via nitric oxide.[4] It might be interesting to evaluate our system with a smaller mixing chamber or with a single soda lime canister serving both as a mixing chamber and nitrogen dioxide scavenger.

A mixing chamber in the system does not necessarily increase nitrogen dioxide production dramatically, provided that adequate mixing is achieved. As nitric oxide oxidation is proportional not only to the contact time with oxygen, but also to the square of its own concentration, even a short peak in nitric oxide may result in considerable nitrogen dioxide production. Consequently, nitric oxide delivery systems using more sophisticated technology such as NODOMO (Drager, Germany), Pulmonox (Messer Griesheim, Austria), the new Ohmeda device (Ohmeda, USA) and the system described by Young,[6] may synchronize nitric oxide flow correctly and generate less nitrogen dioxide. However, these systems require expensive technology such as a mass flow controller and a pneumotachograph[6] or a very fast electronic mixer as in the NODOMO. The latter also has a humidifier in the system which acts as a mixing chamber. The Pulmonox and Ohmeda device measure inspiratory flow and deliver nitric oxide into the inspiratory limb proportional to the latter.

The performance of systems which deliver nitric oxide into the inspiratory limb depend on the accuracy of measuring the ventilator flow pattern (inspiratory time 0.75–1.5 s) and the delay in matching nitric oxide flow (5–20 ml per breath) with the latter. Impaired matching or any mechanical delay in nitric oxide delivery inevitably results in inhomogeneous distribution of concentrated nitric oxide in the inspiratory gases.

In summary, continuous administration of nitric oxide into the tubing of an intermittent flow ventilator resulted in a very fluctuating inspired nitric oxide fraction. Interposition of a mixing chamber may avoid this problem.

# Effects of acute administration of morphine on right atrial catecholamine content and heart rate in chronically morphine-treated rats

J. V. RABADAN, M. V. MILANÉS AND M. L. LAORDEN

## Summary

The purpose of this study was to determine if chronic administration of the preferential μ agonist, morphine, induced changes in cardiac catecholamine content. In rats treated with morphine for 7 days, a challenge dose of morphine 30 mg $kg^{-1}$ i.p. increased atrial noradrenaline (mean 1123.8 (SEM 62.2) ng $g^{-1}$), adrenaline (79.48 (8.5) ng $g^{-1}$) and dopamine (46.0 (1.0) ng $g^{-1}$) content whereas dopamine turnover was decreased; this was accompanied by a decrease in the frequency of contraction of the isolated right atria. There were no changes in noradrenaline, adrenaline, dihydroxy phenylacetic acid (DOPAC) or DOPAC:dopamine ratio in placebo-treated rats. These results demonstrated that acute administration of morphine in morphine-treated rats produced inhibition of neuronal catecholamine activity in the heart which could be responsible for the decrease in atrial contraction frequency. (*Br. J. Anaesth.* 1997; **78**: 439–441).

**Key words**
Sympathetic nervous system, catecholamines. Cardiovascular system, effects. Analgesics opioid, morphine. Rat.

The cellular and molecular basis underlying tolerance to, and physical dependence on, opioids are still uncertain.[1] Thus an alternative mechanism has been sought to explain the development of opioid tolerance/dependence and effects on drug withdrawal, including adaptive changes in neurotransmitter systems that appear to be the target of opioids. Thus in naïve rats, the hypothalamic content of noradrenaline and dopamine was reduced after acute administration of morphine, which suggests that stimulation of opioid receptors produces an increase in the release of these amines in the hypothalamus.[2] In contrast, the morphine-induced reduction in hypothalamic noradrenaline and dopamine concentrations was inhibited in chronically morphine-treated rats, which suggests that tolerance is developed to the effect of the opioid on noradrenergic and dopaminergic neurones.[2] In addition, chronic administration of opioids has been shown to increase, in the locus coeruleus (LC), concentrations of cAMP-dependent protein kinase and substrates for protein kinase, including tyrosine hydroxylase,[3] the rate-limiting enzyme in the biosynthesis of catecholamines. Recent evidence indicates that many of these intracellular adaptations are caused by changes in levels of specific proteins and their mRNA, suggesting that regulation of gene expression, via second messengers, may contribute to tolerance, dependence and withdrawal in the LC.[3]

Although it is well known that catecholamines play a significant role in opioid tolerance and dependence in the central nervous system, little is known of the cardiovascular changes during morphine tolerance or dependence. Previous studies have indicated that catecholamines play an important role in the sympathetic manifestation of the abstinence response in morphine-dependent rats.[4 5]

As the processes involved in tolerance may include the central and peripheral nervous system, this study was undertaken to determine changes in content of noradrenaline, adrenaline, dopamine and its metabolite, dihydroxy phenylacetic acid (DOPAC), in the right atria during morphine tolerance. In addition, we determined if such changes correlated with alterations in atrial contraction frequency in the rat.

## Methods and results

Male Sprague–Dawley rats (200–250 g) were housed four to five per cage under a 12 h light–dark cycle (light 08:00–20.00) in a room with controlled temperature (22±1°C) and humidity (50±10%), and food and water available *ad libitum*. The studies reported in this article were carried out in accordance with the Declaration of Helsinki.

Morphine tolerance was induced by s.c. implantation, under light ether anaesthesia, of pellets containing morphine base (75 mg). The implantation schedule consisted of one pellet on day 0, two pellets on day 2 and three pellets on day 4. Control groups received placebo pellets (lactose) according to the same schedule. Animals were killed on day 7

(08:30–09:00). With this dose schedule, morphine-treated rats show complete tolerance to the effects of morphine.[26] On day 7, rats were treated acutely with saline i.p. or morphine 30 mg $kg^{-1}$ i.p. and killed 30 min later.

There were four experimental groups: (1) chronic placebo–acute saline i.p.;

(2) chronic placebo–acute morphine i.p.; (3) chronic morphine–acute saline i.p.; and (4) chronic morphine–acute morphine i.p.

Noradrenaline, adrenaline, dopamine and DOPAC concentrations were estimated in the right atria of the rat by high pressure liquid chromatography with electrochemical detection (HPLC/ED, Waters Millipore, MA, USA). After decapitation, the chest was opened with a midsternal incision and the right atria were dissected and stored at −80°C until assayed for catecholamines. The right atria were weighed frozen and immediately placed in a dry ice-cooled polypropylene vial and homogenized with a Polytron homogenizer (setting 5 for 30 s) in 1 ml of perchloric acid 0.1 mol $litre^{-1}$ containing EDTA 2.7 mmol $litre^{-1}$ and 3,4 dihydroxy- benzylamine (DHBA 5 pg $\mu l^{-1}$; Waters, MA, USA) as internal standard. The homogenates were centrifuged (15000 rpm, 4°C, 15 min), the supernatant layer was removed into a 1-ml syringe and filtered through a 0.22-μm GV (Millipore), and 10 μl of each sample was injected into a 5 μm $C_{18}$ reverse-phase column (Waters). Electrochemical detection was accomplished with a glassy carbon electrode set at a potential of +0.65 V *vs* the silver–silver chloride reference electrode. The mobile phase consisted of a 95:5 (v/v) mixture of water and methanol with sodium acetate 50 mmol $litre^{-1}$, citric acid 20 mmol $litre^{-1}$, 1-octyl-sodium sulphonate (3.75 mM9, di-n-butylamine 1 mmol $litre^{-1}$) and EDTA 0.135 mmol $litre^{-1}$, adjusted to pH 4.3. Flow rate was 0.9 ml $min^{-1}$. Chromatographic data were analysed with a Waters 740 Date Module integrator and quantified using the peak area ratio of the internal standard. Atrial content of catecholamines was expressed as ng/g wet weight of tissue.

The right atria were isolated and suspended in a 10-ml organ bath. Tyrode solution of the following composition (mmol $litre^{-1}$) was used: NaCl 136.9; KCl 5.0; $MgCl_2$ 1.05; $CaCl_2$ 1.8; $NaH_2PO_4$ 0.4; $NaHCO_3$ 11.9; glucose 5.0. The bathing solution was maintained at 37°C, pH 7.4, and bubbled with 95% oxygen and 5% carbon dioxide. Each preparation was suspended under a resting tension of 0.5 g and equilibrated for 45 min before the start of the experiments. The right atria were beating spontaneously and the frequency of contraction was measured using a force-displacement transducer (Grass FT-03) and recorded on a Letica polygraph.

Concentration–response curves ($10^{-9}$–$10^{-2}$ mol $litre^{-1}$) to morphine were composed for the isolated right atria from chronically morphine-treated rats and from the respective controls chronically treated with lactose pellets.

Each drug concentration was added to the organ bath in a volume of 0.1 ml in a cumulative manner. Concentrations of drugs were increased after a steady-state response had been attained with the previous concentration or after 5 min in the absence of response.

Pellets of morphine base (Alcaliber Labs., Madrid, Spain) or lactose were prepared by the Department of Pharmacy, Clinic Hospital (Madrid, Spain). Morphine (Alcaliber Labs., Madrid, Spain) was prepared fresh every day, dissolved in sterile 0.9% NaCl (saline) or distilled water.

Data are expressed as mean (SEM). Statistical differences in the content of noradrenaline, adrenaline, dopamine, DOPAC and in the DOPAC:dopamine ratio were analysed by two-way analysis of variance followed by the Newman–Keuls *post hoc* test. The results obtained *in vitro* are expressed as a fraction of the change in the frequency of contraction produced by a maximum dose of morphine (mean (SEM) of *n* animals). In this case statistical analysis was performed by one-way analysis of variance followed by the Newman–Keuls *post hoc* test. Differences with a *P* value less than 0.05 were considered significant.

Acute administration of morphine to morphine-treated rats induced an increase ($P<0.01$; $P<0.001$) in atrial content of noradrenaline (1123.8 (62.2) ng $g^{-1}$), adrenaline (79.40 (8.5) ng $g^{-1}$) and dopamine (46.0 (1.0) ng $g^{-1}$), whereas dopamine turnover

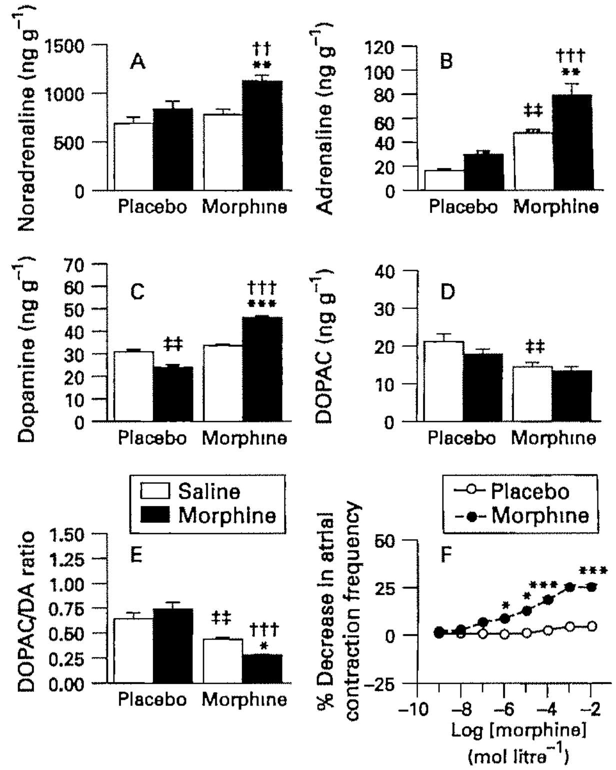

*Figure 1* Atrial noradrenaline (A), adrenaline (B) dopamine (C), DOPAC (D) concentrations and DOPAC/dopamine (DA) ratio (E) in placebo- and morphine-treated rats 30 min after acutely injected saline i.p or morphine 30 mg $kg^{-1}$ i.p. Each bar represents the mean (SEM) of 4–5 experiments. *$P<0.05$, **$P<0.01$, ***$P<0.001$ compared with morphine and saline; ††$P<0.01$; †††$P<0.001$ compared with placebo and morphine; ‡‡$P<0.01$ compared with placebo and saline. (F) Effects of morphine on atrial rate in the isolated right atria from morphine (control rate 250 (1.0) beat $min^{-1}$)- or placebo (control rate 252 (1.2) beat $min^{-1}$)- treated rats. Each point represents the mean (SEM) of five experiments for each experimental group. *$P<0.05$, ***$P<0.001$ compared with placebo.

(0.28 (0.01) ng $g^{-1}$) was decreased ($P<0.05$; $P<0.01$) compared with morphine-pretreated animals injected acutely with saline or placebo-treated rats given morphine. Administration of morphine to placebo-treated rats decreased ($P<0.01$) the content of dopamine (24.0 (1.7) ng $g^{-1}$) without significant changes in the concentrations of noradrenaline (844.20 (69.5) ng $g^{-1}$), adrenaline (29.6 (2.9) ng $g^{-1}$), DOPAC (17.66 (1.4) ng $g^{-1}$) or the DOPAC:dopamine ratio (0.74 (0.07) ng $g^{-1}$) compared with control groups given saline (fig. 1).

Concentration–response curves for morphine $10^{-9}$–$10^{-2}$ mol $\text{litre}^{-1}$ were obtained in placebo- or morphine-treated rats. In placebo-treated animals, morphine $10^{-9}$–$10^{-5}$ mol $\text{litre}^{-1}$ did not change atrial contraction frequency in the right atria. Higher concentration of morphine induced a small decrease (5 (0.5) %). However, in the morphine-treated rats, morphine induced a significant ($P<0.05$; $P<0.001$) decrease in atrial contraction frequency at concentrations of $10^{-6}$ –$10^{-2}$ mol $\text{litre}^{-1}$. The maximum effect was 25 (1.3) % (fig. 1).

## Comment

We conclude that acute administration of morphine in morphine-treated rats produced inhibition of neuronal catecholamine activity in the heart which could be responsible for the decrease in atrial contraction frequency.

CASE REPORTS

# Obstructive sleep apnoea syndrome: is this an overlooked cause of desaturation in the immediate postoperative period?

K. VIDHANI AND B. T. LANGHAM

## Summary

We report the case of a 38-yr-old man who presented for an emergency mastoidectomy and suffered from severe upper airways obstruction in the postoperative period. Subsequent questioning revealed a history of heroic snoring and further investigations proved a diagnosis of obstructive sleep apnoea. (*Br. J. Anaesth.* 1997; **78**: 442–443).

**Key words**
Ventilation, apnoea. Sleep apnoea. Airway, obstruction. Complications, obstructive sleep apnoea.

Patients with obstructive sleep apnoea are classically obese and complain of hypersomnolence and severe heroic snoring. Surgical treatment of these patients is becoming common place and their anaesthetic management is well defined. However, not all patients present a classical picture and we discuss a mode of presentation after anaesthesia in a previously undiagnosed patient.

## Case report

A 38-yr-old man presented for anaesthesia for an emergency mastoid operation. Preoperative assessment showed him to be 183 cm in height, weighing 96 kg and of muscular build (body mass index 28). He had undergone previous uneventful general anaesthesia with a Cormack and Lehane[1] view at laryngoscopy of grade 2, 4 yr previously. On examination of the oropharynx he had a Mallampati[2] score of 2, good mouth opening and normal dentition. His general health was good although he admitted to smoking 30 cigarettes per day and was receiving cimetidine for sporadic dyspepsia. All investigations were normal.

Standard monitoring was applied in the anaesthetic room and a vein cannulated. The patient's lungs were preoxygenated and rapid sequence induction with thiopentone 500 mg and suxamethonium 100 mg and cricoid pressure was carried out. Laryngoscopy proved difficult because of inability to lift the epiglottis from the posterior pharyngeal wall. Intubation was accomplished by passing the laryngoscope beyond the epiglottis as with a Magill blade. On return of neuromuscular function a dose of atracurium 50 mg was given and the patient's lungs were ventilated using a Nuffield Penlon ventilator via a Bains breathing system with 1–2% isoflurane and 70% nitrous oxide in oxygen. End-tidal carbon dioxide partial pressure was maintained at 4.5 kPa. Analgesia was provided by morphine 10 mg i.v., and droperidol 1 mg was given for postoperative nausea and vomiting. Arterial pressure was maintained at 100 mm Hg systolic at the request of the surgeon. At the end of the procedure residual neuromuscular block was antagonized with neostigmine 2.5 mg and glycopyrronium 0.5 mg was given. The patient was allowed to wake up and the trachea extubated on his side when it was judged that full neuromuscular function had returned.

On extubation he became agitated and had noisy breathing resembling severe snoring with flaring of the nostrils and associated desaturation. At this point we decided it was important to examine the upper airway to exclude obstruction. Anaesthesia was again induced using isoflurane in 100 % oxygen. On laryngoscopy there was no foreign body or swelling present in the upper airway and the epiglottis and larynx appeared normal. A nasal and oral airway were inserted and a normal respiratory pattern with good tidal volumes and an $Sp_{O_2}$ of 100% were obtained. The patient was allowed to wake up. However, when the patient was awake enough to spit out the airways he again developed severe upper airways obstruction and the trachea was reintubated rapidly using propofol 150 mg, suxamethonium 100 mg and atropine 0.6 mg. As there was found to be nothing obstructing the airway it was decided to allow the patient to wake up and self extubate in a sitting position. This was successfully achieved but the apparent upper airways obstruction recurred with a decrease in $Sp_{O_2}$. The MIE anaesthetic face mask was applied tightly to the patient's face with the Heidbrink valve partially closed. This manoeuvre improved the patient's condition and consequently he was admitted to the intensive care unit for oxygen therapy with +5 cm $H_2O$ of CPAP. He was also given dexamethasone 16 mg to reduce soft tissue swelling from repeated

*Present address: Derbyshire Royal Infirmary, London Road, Derby.

laryngoscopy. A lateral soft tissue neck x-ray showed no abnormality. Over the next 12 h the upper airway "snoring" subsided and the patient returned to the postoperative ward the following day.

On questioning the patient and his partner in the postoperative period a history of severe snoring became apparent, such that the sleep of the partner was seriously disturbed. There were no other features of obstructive sleep apnoea. Subsequently the patient was referred to the sleep studies laboratory. Overnight $Sp_{O_2}$ monitoring (the standard test carried out in this hospital for diagnosis of obstructive sleep apnoea) revealed periods of desaturation consistent with a diagnosis of mild obstructive sleep apnoea with a minimum $Sp_{O_2}$ of 78%, mean $Sp_{O_2}$ of 91% and an average of 31 dips $h^{-1}$. A trial of nasal CPAP+7.5 cm $H_2O$ achieved satisfactory oxygenation.

## Discussion

Obstructive sleep apnoea is a common but often undiagnosed condition that may affect 1% of the population.[3] The major problem is that of episodic hypopnoea or apnoea during sleep, the cause of which usually results from partial or complete obstruction of the upper airway. The clinical features include loud snoring (95%), day-time sleepiness (90%), unrefreshing and restless sleep (40%), morning headache, nocturnal choking, reduced libido, morning drunkenness, ankle swelling and enuresis. The syndrome occurs in all ages but is most common in late middle age, the male population and the obese, although it is well recognized that the patient need not be obese or somnolent to have significant sleep fragmentation or airway obstruction.

Problems may occur during induction of anaesthesia, in particular difficult intubation[4] and maintenance of the airway because of associated anatomical problems. Maintenance of anaesthesia requires controlled ventilation as spontaneous ventilation may lead to profound underventilation, acidosis, hypercapnia and hypoxia.[5] Before extubation patients should be awake and extubation should be in the sitting or lateral position. After operation, loss of the upper airway may still occur as oedema in this region may accumulate. Patients may benefit from nasal CPAP at this point and the majority of these patients with a known diagnosis of obstructive sleep apnoea should be managed in the intensive care unit or the high dependency unit for a variable period.

Our patient was seen in the preoperative period and presented no clinical features of obstructive sleep apnoea. He was of muscular build, did not appear obese and assessment of his airway revealed no abnormal features suggestive of a difficult intubation. He was anaesthetized 4 yr previously when intubation had been carried out successfully and anaesthesia had been uneventful. During our anaesthetic, intubation had proved more difficult with the laryngeal inlet being obscured by the epiglottis and requiring two attempts at intubation. Maintenance of anaesthesia was uneventful but extubation and the subsequent period proved difficult with upper airway obstruction. During this period we considered the likely causes of this problem to be: obstruction at the lips, obstruction by the tongue, obstruction above the glottis by a foreign body, saliva, vomitus, blood or oedema and obstruction at the glottis.[6] Repeat laryngoscopy excluded these causes and a clear airway was maintained while the patient was deeply anaesthetized with an airway *in situ*. The problem recurred when the airway was rejected by the patient. As we have stated the larynx was reintubated and then extubated with the patient fully awake in the sitting position and CPAP applied. At this point we considered a diagnosis of obstructive sleep apnoea and we feel that the initial difficulty with intubation had exacerbated his previously undiagnosed condition by causing minimal oedema of the upper airway, most likely the tongue. Subsequent investigation proved that this patient had obstructive sleep apnoea syndrome.

A diagnosis of obstructive sleep apnoea has often been made when these patients present for surgery, which may be of a corrective nature for their underlying diagnosis and as a consequence appropriate anaesthetic measures may be taken. Our patient was undiagnosed and appeared to have no features that would raise suspicion of obstructive sleep apnoea. However, on postoperative questioning he admitted to heroic snoring (a feature that occurs in 95% of cases), and had we obtained this history in our preoperative assessment our anaesthetic management would have been altered appropriately. This would have included minimizing the use of opioid analgesia (using NSAID and local anaesthetic infiltration), ensuring the patient was fully awake in the sitting position before extubation with a means of delivering CPAP if required and an appropriate safe environment for the patient in the postoperative period. We therefore agree with Dodds[5] that the question "Do you snore" should be asked in all preoperative assessments.

# Intentional asystole during endoluminal thoracic aortic surgery without cardiopulmonary bypass

A. B. BAKER, M. J. BOOKALLIL AND G. LLOYD

## Summary

We describe in three patients the use of adenosine to arrest the heart without cardiopulmonary bypass during endoluminal repair of thoracic aortic aneurysms. The pharmacology of adenosine, a purine nucleoside present in all cells, is reviewed briefly, with special reference to its use in causing transient asystole, which is required for successful surgical expansion of the graft stent in the thoracic aorta. (*Br. J. Anaesth.* 1997; **78**: 444–448).

**Key words**
Pharmacology, adenosine. Surgery, vascular.

The advent of endoluminal grafting of the aorta[1] has required new approaches to the anaesthetic management of patients, particularly during balloon expansion of the aortic stent when arterial pressure must be reduced to prevent misplacement of the stent and damage to the proximal aorta or heart. We report three patients who received i.v. bolus doses of adenosine with the intention of causing asystole and hypotension at the time of expansion of the aortic stent of endoluminal grafts to the thoracic aorta.

Adenosine ("Adenocor" Sanofi Winthrop Pty Ltd), which is a relatively new antiarrhythmic agent for treating supraventricular tachycardia, is a naturally occurring purine nucleoside which transiently inhibits adenyl cyclase and 3, 5-cyclic adenosine monophosphate (cAMP) by binding to adenosine receptors, and has been shown to have major cardiovascular actions[2 3] (depression of sinoatrial (SA) and atrioventricular (AV) nodes; reduction in atrial contractility; attenuation of catecholamine effects primarily on the ventricles; depression of ventricular automaticity; and attenuation, via a presynaptic action, of adrenaline-induced noradrenaline release). The short duration of action, short half-life and effects on heart conduction make adenosine a useful drug in the diagnosis and management of supraventricular tachycardias such as Wolff–Parkinson–White syndrome.[4 5] Adenosine has also been useful in myocardial preservation during cardiac surgery because of cardiac arrest with a hyperpolarized myocardium rather than the more usual depolarized state,[6] although this has been challenged.[7]

## Case reports

### PATIENT NO. 1

A 38-yr-old female presented with an aneurysm of the thoracic aorta just distal to a previous coarctation which had been repaired at the age of 6 yr. Angiography showed normal coronary arteries and ventricular function. She was receiving ramipril 5 mg mane and oxazepam 15 mg mane. Preoperative creatinine concentration was 61 μmol $\text{litre}^{-1}$ (increasing to 69 μmol $\text{litre}^{-1}$ after operation), haemoglobin 129 g $\text{litre}^{-1}$ (decreasing to 87 g $\text{litre}^{-1}$, 3 days after operation even with transfusion during operation), and platelets $320 \times 10^9$ $\text{litre}^{-1}$ (decreasing to $188 \times 10^9$ $\text{litre}^{-1}$, 2 days after operation). After premedication with papaveretum 15 mg and hyoscine 0.3 mg, anaesthesia consisted of tracheal intubation using thiopentone and tubocurarine block, and isoflurane and nitrous oxide in oxygen. Intra-arterial, pulmonary arterial, capillary wedge and central venous pressures were measured.

Surgical access was via surgical exposure of the left common iliac artery, and percutaneous cannulation of the right brachial artery. Adenosine was used at the time of balloon inflation to expand the stents in the descending thoracic aorta. Two grafts (White-Yu GAD 22 mm×7 mm) were used, one inside the distal part of the other (the so-called trombone technique).[8] With the patient heparinized, receiving 100% oxygen, and after a trial dose (of 12 mg) administered via the pulmonary artery catheter to determine the correct dose to stop the heart for the required time of 20–30 s, this dose of adenosine 12 mg was then used on two occasions at the time of balloon inflation of the stent grafts. Pulse oximetry demonstrated that $Sp_{O_2}$ always exceeded 99% at this time and her temperature was 34.5 °C from environmental cooling only. There were no adverse complications of the use of adenosine. In the early postoperative phase the patient developed a small left basal pleural effusion, and at 6 days after

operation she required a right brachial artery thrombectomy (10 cm thrombus) which was related most probably to the brachial artery sheath used for surgical access in that arm. She was discharged 10 days after her original aortic operation. Six month surgical follow-up showed that the aneurysmal sac had been isolated.

### PATIENT NO. 2

A 66-yr-old male presented with a recurrent thoracic aortic aneurysm just distal to the site of a previous open repair under cardiopulmonary bypass performed 3 yr previously for a chronic dissection. This first repair was immediately distal to the left subclavian artery. At angiography the coronary arteries were normal and there was normal ventricular function. The patient also had non-insulin dependent diabetes mellitus and glaucoma, and was receiving atenolol 100 mg, ramipril 5 mg and aspirin 100 mg mane, loratidine 10 mg daily, mebeverine 135 mg as needed, 0.25% timolol eye drops twice daily and temazepam 10–20 mg at night. Preoperative creatinine was 121 μmol litre$^{-1}$ (increasing to 182 μmol litre$^{-1}$ after operation), haemoglobin 121 g litre$^{-1}$ (decreasing to 73 g litre$^{-1}$, 2 days after operation, and then increasing to 92 g litre$^{-1}$, 4 days after operation, all without blood transfusion) and platelets $113\times10^9$ litre$^{-1}$ (decreasing to $64\times10^9$ litre$^{-1}$, 2 days after operation, and then increasing to $102\times10^9$ litre$^{-1}$, 4 days after operation). After premedication with papaveretum 15 mg and hyoscine 0.3 mg, anaesthesia consisted of placement of a thoracic extradural with the intention of using lignocaine to block the cardiac sympathetic nerves, tracheal intubation using thiopentone and tubocurarine/pancuronium block, and low-flow oxygen and nitrous oxide with isoflurane. Intra-arterial, pulmonary arterial, capillary wedge and central venous pressures were measured.

Surgical access was via the right common femoral artery. Adenosine was used at the time of balloon inflation to expand the stents in the descending thoracic aorta. Two grafts were used, one inside the distal part of the other (White-Yu GAD 30 mm×12.5 mm).[8] With the patient heparinized, receiving 100% oxygen, and after trial doses of 9, 15, 24, 36 and 45 mg administered peripherally via an arm vein to determine the correct dose to stop the heart for the required time of 20–30 s, a dose of adenosine 45 mg was used on each occasion at the time of balloon inflation to expand the stent grafts. The patient's oxygen saturation was never less than 100% at this time and his temperature was 35.5 °C, again solely from environmental conditions. There were no adverse complications of the procedure. The patient was nursed initially in the ICU with IPPV overnight. The tracheal tube was removed on the first postoperative day and the patient transferred to the ward on the second day and discharged from hospital on the fifth postoperative day. Six month surgical follow-up showed that the aneurysmal sac had been isolated.

### PATIENT NO. 3

A 51-yr-old male with Marfan's syndrome who had previously undergone two aortic valve replacements 17 and 12 yr earlier, and an abdominal aortic repair 10 yr previously, presented with acute dissection of his thoracic aorta which required a Bentall's procedure (replacement of the aortic valve and ascending aorta in continuity); 22 days later, while still in hospital, a further deterioration with interscapular back pain and angiographic and ultrasound evidence of a rapidly expanding thoracic aortic aneurysm required endoluminal repair. This endoluminal repair was immediately distal to the left subclavian artery. At angiography the coronary arteries were normal with moderately impaired left ventricular function. The patient was receiving i.v. heparin, and captopril 50 mg three times daily, sotalol 80 mg twice daily, diltiazem 240 mg mane, amiloride 5 mg mane, frusemide 40 mg twice daily, minoxidil 10 mg twice daily, atenolol 100 mg mane, digoxin 25 μg mane and allopurinol 300 mg mane. Preoperative creatinine was 67 μmol litre$^{-1}$ (increasing to 182 μmol litre$^{-1}$ after operation), haemoglobin 89 g litre$^{-1}$ (decreasing to 73 g litre$^{-1}$, 2 days after operation, and then increasing to 92 g litre$^{-1}$, 4 days after operation, all without blood transfusion) and platelets $365\times10^9$ litre$^{-1}$ (decreasing to $64\times10^9$ litre$^{-1}$, 2 days after operation, and then increasing to $102\times10^9$ litre$^{-1}$, 4 days after operation). After premedication with papaveretum 15 mg and hyoscine 0.3 mg, anaesthesia consisted of tracheal intubation using thiopentone and tubocurarine/pancuronium block and low flow oxygen and nitrous oxide with isoflurane. Intra-arterial, pulmonary arterial, capillary wedge and central venous pressures were measured.

Surgical access was via the left common femoral artery and right brachial artery. Adenosine was used at the time of balloon inflation to expand the stents in the descending thoracic aorta. Two grafts were used, one inside the distal part of the other (White-Yu GAD 24 mm×15 mm and 24 mm×7 mm).[8] With the patient heparinized, receiving 100% oxygen, and after trial doses of 9 and 15 mg administered centrally via the pulmonary artery catheter to determine the correct dose to stop the heart for the required time of 20–30 s, a dose of adenosine 21 mg was used on the first occasion and 27 mg on the second occasion at the time of balloon inflation to expand the stent grafts. The patient's oxygen saturation was never less than 100% at this time and his temperature was 35.5 °C, again solely from environmental conditions. There were no adverse complications of the procedure. The patient was nursed initially in the ICU but his trachea was not intubated or his lungs ventilated. The patient was transferred to the ward the next day and discharged from hospital on the fifth postoperative day.

## Discussion

Parodi, Palmaz and Barone[9] introduced endoluminal grafting of the aorta after animal experimentation by several groups,[10–14] and surgeons at our hospital have performed more than 150 abdominal aortic grafts.[15] Recently, repair of the thoracic aorta has also been performed by the endoluminal technique,[16 17] and this operation has required further evaluation of the place of hypotension at the time of expansion of the aortic stent to prevent both displacement of the stent and major damage to the aorta or undue strain on the myocardium leading to ischaemia or infarction.[18 19] If the stent is moved by the pressure of blood in the aorta forcing the inflating balloon distally at the time of expansion of the graft stent, there may be major problems in placement of the graft which is measured precisely before insertion. There may also be major problems, with aortic rupture or dissection, because of increased pressure in the aorta caused by balloon obstruction. The heart may also be stressed because of the increased demands on contractility and myocardial oxygen at the time of aortic obstruction by the balloon.[18 19] For endoluminal grafting of the abdominal aorta various anaesthetic hypotensive techniques, such as the use of sodium nitroprusside, glyceryl trinitrate, heavy volatile anaesthetic dose, and both lumbar and thoracic extradural block, have been used to reduce arterial pressure at the time of balloon inflation to expand the graft stent.

The work of Dorros and Cohn[20] during endoluminal grafting of the thoracic aorta suggested that adenosine would be an ideal agent to use to reduce arterial pressure by stopping the heart during surgical expansion of the proximal stent of the graft, which in these cases was to be by balloon inflation totally obstructing the thoracic aortic outflow. Adenosine occurs naturally in all cells, has no negative inotropic effects, has transient actions and decreases arterial pressure dramatically by causing asystole when given in high doses.[21] The pharmacology of adenosine is species specific but there appear to be two main adenosine receptors[21 22]—the $A_1$ receptor leading to inhibition of adenylate cyclase and thus decreased production of cAMP which is the dominant effect on cardiac electrophysiology[23] and the $A_2$ receptor leading to stimulation of adenylate cyclase and increased cAMP which is the dominant effect on vasodilatation. Recently in the rat there was a suggestion that there is a separate $A_3$ receptor mediating decreases in arterial pressure.[24] There are also effects on $K^+$ channels in the heart inducing an outward potassium current and hyperpolarization of the cell membrane.[23] Hepatic and renal insufficiency do not affect duration of action, as adenosine is taken up and metabolized by red blood cells and vascular endothelium, with a half-life of approximately 2–10 s in low doses but increasing with higher doses to approximately 2 min.[25–27] Adenosine either enters the nucleotide pool by phosphorylation to AMP or is metabolized primarily to inosine, hypoxanthine, xanthine and ultimately uric acid.[22] Side effects of adenosine are transient SA node inactivity, atrial fibrillation, hypotension and flushing, and in the awake patient headache, transient chest pain and dyspnoea.[5] In larger doses adenosine produces suppression of SA node automaticity which is short lived. Adenosine should be used with caution in patients with bronchial asthma because inhaled adenosine has precipitated asthma,[28] and in patients with sick sinus syndrome or second- or third-degree heart block unless there is a pacemaker inserted. Patients receiving methylxanthines are resistant to adenosine because of competitive inhibition of $A_1$ and $A_2$ adenosine receptors, and patients receiving dipyridamole may have prolonged asystole with adenosine because of inhibition of the transport system into cells, with subsequent increases in adenosine concentrations.[22 29] Slow channel calcium blocking agents such as verapamil and nifedipine also inhibit the transport of adenosine into cells.[30] Benzodiazepines enhance the effects of adenosine[22] and carbamazepine is reported in the company's product information leaflet also to increase the degree of heart block.

Potentially, patients who have endoluminal repair of the thoracic aortic may need to have this procedure converted to open surgical repair if there is sudden rupture of the diseased aorta by intra-aortic surgical manipulations or if there are other surgical problems with placement of the endoluminal graft. Thus anaesthesia techniques need to take such possibilities into account when preparing the patient for surgery. This was the main reason why our second patient had a thoracic extradural inserted, although extradural block of the cardiac sympathetics was also planned to assist with myocardial function, lower contractility and myocardial oxygen demand, and improve myocardial blood flow.[31] In addition, there may be a synergistic reduction in arterial pressure with administration of adenosine, which may prevent hypertension overcompensation on recovery from adenosine asystole.

Dorros and Cohn[20] recommended insertion of a temporary pacemaker before administration of adenosine. Our cardiological advice was that this was not necessary if an external pacing source was readily available, as it was most unlikely that the asystole would be prolonged in these patients who did not have any predisposing problems such as heart block or sick sinus syndrome.

The normal dose of adenosine for termination of supraventricular tachycardias is 3–6 mg and in some patients this dose has caused transient asystole. Larger doses cause some hypotension because of decreased peripheral vascular resistance even when asystole is not produced. The dose of adenosine to be used during expansion of the stent must be determined before the surgical manoeuvre, otherwise the duration of asystole and hence surgical time are unpredictable. Because the dose of adenosine required to produce asystole and the duration of asystole are unpredictable it is preferable to start with a dose of 9 mg, increasing in steps until asystole of the desired duration of approximately 20–30 s is produced. Our second patient proved relatively resistant requiring larger doses of adenosine than previously recommended,[20] but this may have been caused by administration of adenosine via a peripheral vein in this patient. Rankin and colleagues[32] showed that lower doses were needed (by a factor of one-third—3 mg *vs* 10 mg) when adenosine was administered centrally rather than peripherally, and we intend to give adenosine via a central vein in future. This patient was not receiving any drug therapy, such as methylxanthine, which has been reported to antagonize adenosine.[22] Another possible cause for the increased dose of adenosine in our second patient was the use of a thoracic extradural with full sympathetic block of the heart, as adenosine effects are reported to be more prominent when there is increased sympathetic tone.[33]

There were no apparent cardiac, vascular or neurological sequelae to cessation of cardiac output for periods up to 45 s in our patients who were not specifically protected by hypothermic techniques throughout surgery, although mild hypothermia occurred in both patients, which may have had some protective effect on cerebral metabolism.[34] Life-threatening events after adenosine would appear to be rare[35] and although minor side effects are common in awake patients, most of these symptoms and signs are masked during anaesthesia. The major complications which are possible after this technique using adenosine would be fatal arrhythmias, thromboembolism, cerebral ischaemia or infarction, coronary ischaemia or infarction, stroke or paraplegia. All of these complications are possible with any surgical repair of thoracic aortic aneurysms, and we believe that in the endoluminal surgical repair they may be less likely or at least no more likely to occur than in standard open repair of the thoracic aorta with or without cardiopulmonary bypass. Caution in the use of adenosine in this way to cause asystole intentionally should be exercised in patients with cerebrovascular or cardiac ischaemia which could potentially be exacerbated by the period of hypotension and circulatory arrest, although adenosine has been used for both cerebral and coronary protection against ischaemic damage.[36 37] These contraindications should be borne in mind when surgeons are contemplating the use of adenosine in endoluminal thoracic aortic repair, as Dorros and Cohn[20] have recommended that adenosine should be used in all aortic repairs by the endoluminal technique, including abdominal. White,[38] in a commentary on their article, cautioned that such sweeping recommendations may be "detrimental to the wider application and appeal of the endoluminal technique". In any case it would appear to be unnecessary in endoluminal repair of the abdominal aorta.[1 8 15]

We believe that the use of adenosine in considered cases of endoluminal repair of the thoracic aorta enhances the management of balloon inflation of the graft stent to allow better expansion to match the aortic diameter. This technique has the advantages of controlled transient hypotension with potential protection of the heart and brain.

EQUIPMENT

# A new method for measurement of anaesthetic partial pressure in blood

M. A. SMITH, S. M. SAPSED-BYRNE AND G. G. LOCKWOOD

## Summary

We have developed a simple, reliable method for rapid analysis of the partial pressure of volatile anaesthetic agents, based on a two-stage, headspace analysis. It is designed to solve the problems associated with reduced solubility of modern anaesthetics. After equilibration and analysis of a 2-ml sample of blood at 37 °C, 1 ml is transferred to another vial for a second equilibration. This ensures that there is no vapour in the headspace before the second equilibration. Measurements were performed on human blood samples equilibrated with 1% sevoflurane, 2.5% isoflurane or 3% desflurane in a tonometer. The mean error in the sample measurements was −2.3% of the tono-meter reading and the 95% confidence interval for an individual measurement was ±8.5%. Blood samples may be stored overnight without any significant change in the results. (*Br. J. Anaesth.* 1997; **78**: 449–452).

**Key words**
Anaesthetics volatile, isoflurane. Anaesthetics volatile, desflurane Anaesthetics volatile, sevoflurane. Measurement techniques, partial pressure.

The rarity of clinical studies which measure partial pressures of anaesthetics in blood is a testimony to the troublesome nature of the assay. Blood content can be measured relatively simply by comparison, but partial pressure can be calculated only if the blood-gas partition coefficient is known. The classical headspace analysis technique for measurement of partial pressure involves equilibrating the anaesthetic between the blood sample and air (the headspace) within the containing vessel.[1 2] The partial pressure in the headspace can then be measured easily, but is no longer equal to the initial partial pressure in the blood sample. However, if the headspace is repeatedly flushed with fresh gas and repeated equilibrations performed, then a curve of the exponential washout of the anaesthetic from the blood can be plotted. Projecting this curve one step backwards from the first equilibration should give the initial partial pressure of the anaesthetic vapour. The blood-gas solubility of the sample can be determined from the rate of washout if the volumes of blood and headspace are known. Blood can be equilibrated within the glass syringe used to obtain the sample[1 2] (which has the advantage of maintaining ambient pressure in the headspace) or it can be transferred to a vial sealed with a PTFE-faced septum[3] (which has a cost advantage). If the ratio of air to blood is very small, such as when a bubble is introduced into a syringe of blood and allowed to equilibrate, the reduction in partial pressure of anaesthetic within the blood is negligible and a single step measurement is adequate.[4] We have found this technique troublesome in practice and in principle it is less appropriate for less soluble anaesthetics.

When we measured partial pressures using this classical technique our results grossly underestimated the partial pressure of desflurane in blood equilibrated in a tonometer, even though we were able to measure isoflurane partial pressures reasonably accurately. We thought that the error may be caused by trapping of desflurane in bubbles which prevented efficient flushing of the headspace between equilibrations. This would have a greater effect with desflurane than isoflurane because there is more desflurane in the gas within a bubble than in an equivalent volume of blood—the reverse is the case for isoflurane. We describe a simple method for accurate, reproducible and rapid analysis of the partial pressure of a volatile anaesthetic in small volumes of blood which does not depend on an assumed blood-gas partition coefficient.

## Methods

### EQUIPMENT

All gas samples were analysed using a Pye Series 204 gas chromatograph. The carrier gas was nitrogen flowing at 30 ml min$^{-1}$. A 0.9-m glass column (2 mm id) packed with 3% OV-17 on GasChromQ was maintained at 125 °C, producing a retention time of 0.5 min. The volatile agent was detected by a flame ionization detector operating at 175 °C. All samples were injected into a 20-µl sampling loop (Valco) on the chromatograph inlet using a 100-µl

gas-tight syringe fitted with a valve (SGE, Melbourne).

Blood samples were prepared by equilibration in an IL-237 tonometer. A 2.5-ml gas-tight syringe (SGE, Melbourne) was used to transfer blood from the tonometer and between vials.

A cylinder of isoflurane in air was prepared and used as a standard to confirm stability of the gas chromatograph throughout the measurements. An approximate measurement of its concentration was made using a Datex Ultima (Datex Instrumentarium, Helsinki), calibrated according to the manufacturer's recommendations.

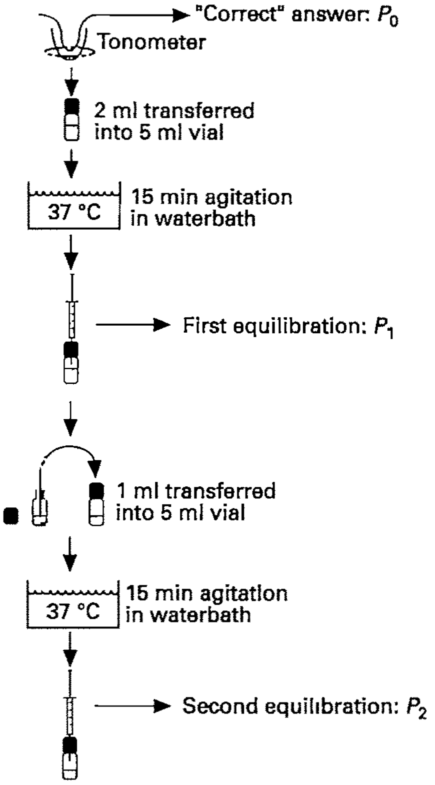
### PREPARATION OF BLOOD SAMPLES

Blood was obtained (with the approval of the chairman of the local Research Ethics Committee) from healthy volunteers and patients undergoing major surgery. A 6-ml blood sample was placed in the tonometer and allowed to equilibrate with a gas mixture flowing at 200 ml min$^{-1}$ for a period of 15 min. Mixtures of 1% sevoflurane, 2.5% isoflurane or 3% desflurane in air, and a mixture of 3% desflurane, 5% carbon dioxide and 21% oxygen (balance nitrogen) were used. A gas sample was obtained from the outflow of the equilibration chamber into the 100-µl syringe and injected into the gas chromatograph. This was taken to be the "true" partial pressure of anaesthetic in the blood. Two 2-ml aliquots of blood were then transferred accurately into nominally 5-ml vials (mean 4.77 (SEM 0.01) ml, measured by water displacement) and closed by a screw cap sealed with a Teflon-faced septum. The analysis was generally undertaken immediately but in order to investigate the effect of delay in measurement, one sample of some pairs was stored in a refrigerator and analysed 24 h later.

### ANALYSIS TECHNIQUE

The vials were agitated in a water bath at 37 °C for 1 min. Headspace gas was then sampled using a 100-µl syringe by puncturing the vial septum and making several movements of the plunger. Two samples were obtained and injected into the gas chromatograph: the greater reading (almost invariably the first, but differences were generally less than 2%) was used in the calculations. Exactly 1 ml of blood was transferred into another 5-ml vial and sealed with a new cap and septum for a second period of equilibration at 37 °C and subsequent analysis of the headspace gas (see fig. 1). The syringe was flushed several times with room air between samples to avoid carry over, and frequent air samples were injected into the gas chromatograph to confirm that syringe contamination was negligible.

### CALCULATIONS



"Correct" answer: $P_0$
Tonometer
2 ml transferred into 5 ml vial
37 °C
15 min agitation in waterbath
First equilibration: $P_1$
1 ml transferred into 5 ml vial
37 °C
15 min agitation in waterbath
Second equilibration: $P_2$

*Figure 1* Methodology flowchart.

When the sample is equilibrated in the water bath the pressure within the headspace increases because of warming, humidification and exchange of gases with the blood sample. When the headspace sample is injected into the gas chromatograph it is at room temperature and pressure: the concentration of desflurane is unchanged but the partial pressure is reduced, so the chromatograph reading must be increased to compensate for this. The increase in pressure caused by temperature should be given by a factor of:

$$(273+37)\ /\ (273+T_{\text{lab}})$$

where $T_{\text{lab}}$=laboratory temperature in Celsius and typically gives a 5% increase. Humidification increases pressure by 6 kPa, but when the sample is aspirated into the chromatography syringe it cools and the vapour pressure of water reduces to approximately 3 kPa, and our calculations include this factor to correct for the "dilution" of the anaesthetic by water vapour in the headspace sample.

Carbon dioxide in blood also equilibrates with the headspace increasing the total headspace pressure. Some correction for this should be made, but the relationship between carbon dioxide content and tension is complex. We have crudely assumed that the content is 0.1 ml (ml of blood)$^{-1}$ kPa$^{-1}$. Then a 2-ml blood sample equilibrated with xkPa carbon dioxide contains 0.2x ml of carbon dioxide. After equilibration with 3 ml headspace the total vial carbon dioxide content is $0.2y+3y/101.3$, where y=carbon dioxide tension after equilibration in kPa. Assuming that no carbon dioxide is lost from the vial we deduce that $y=0.2x/0.23=0.87x$, so the pressure within the headspace increases by 0.87 of the fractional partial pressure of carbon dioxide in blood before the first equilibration. A similar effect occurs during the second equilibration, although the volumes of blood and headspace have changed, and we allow for an increase in headspace pressure of 0.63x at the time the second sample is obtained. Finally, the volatile anaesthetic itself increases the headspace pressure (although this is only likely to be important for desflurane). Conversion of gas chromatograph counts to partial pressure of the syringe sample ($P_{\text{syringe}}$) is achieved by sampling intermittently from a cylinder containing a known concentration of the vapour concerned. $P_{\text{syringe}}$ is converted to partial pressure within the vial ($P_{\text{vial}}$) by

$$P_{\text{vial}}=P_{\text{syringe}}\times 310\,/\,(273+T_{\text{lab}})\times(1+F_{\text{water}}+F\text{CO}_2+F_{\text{anaesthetic}})$$

where $F_{\text{water}}$ is taken to be 0.03, $F\text{CO}_2$=fractional carbon dioxide tension in the vial, and $F_{\text{anaesthetic}}$ is taken to be $P_{\text{syringe}}$ expressed as a fraction of ambient pressure.

Simple back projection no longer works because the ratio of blood to air is not constant. Let $P_0$ be the partial pressure of desflurane in the sample when it was first drawn; let $P_1$ and $P_2$ be the partial pressures in the vial after the first and second equilibrations, respectively; let $V_v$, $V_1$ and $V_2$ be the volumes of the vial, the first blood sample (2 ml) and the sample transferred (1 ml), respectively; let λ be the blood gas coefficient at 37°C. The gas chromatograph readings are corrected for pressure changes in the vial caused by humidification and warming of air. Then equating the amount of desflurane in the vial before and after each equilibration:

$$P_0V_1\lambda=P_1V_1\lambda+P_1(V_v-V_1)$$

and

$$P_1V_2\lambda=P_2V_2\lambda+P_2(V_v-V_2)$$

The second equation is solved for λ and this value is used to determine $P_0$ in the first. The calculations were performed using Microsoft Excel v4.

## Results

Data are presented as percentage of the tonometer concentration and are shown in figure 2. Analysis of variance revealed no difference between the results for the different anaesthetics. Overall the mean error of the 93 samples was 2.3%, with the 95% confidence interval of the mean (−3.2%, −1.4%) failing to include zero, that is there was a systematic error. The mean difference (confidence interval of the mean) between 11 paired samples analysed 24 h apart was 2.0% (−0.8%, +4.8%) of the tonometer reading.

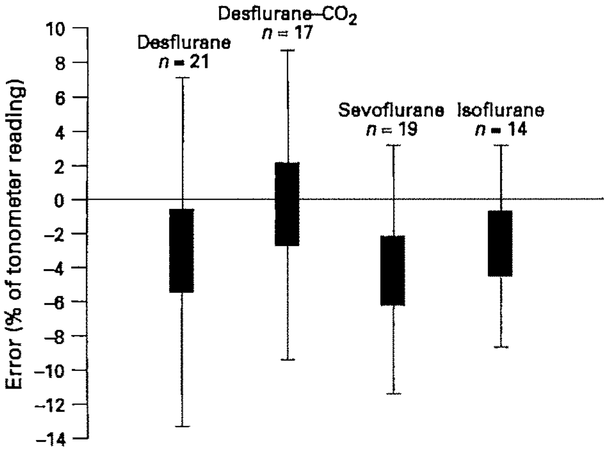


*Figure 2* Results from the four equilibration gas mixtures. The solid bars indicate the 95% confidence interval of the mean, the error bars indicate the 95% prediction interval for an individual measurement.

## Discussion

When we attempted to measure the partial pressure of desflurane using the method described by Landon and colleagues for isoflurane,[3] we consistently obtained values less than the tonometer. We blamed incomplete flushing of the headspace between equilibrations caused by trapping of desflurane vapour in froth and bubbles, noting that such errors are more significant the less soluble the agent. We therefore decided to transfer an aliquot of blood to a new vial to overcome this problem.

When the samples are equilibrated in vials it is necessary to allow for pressure changes in the headspace. Our corrections for this are exclusively based on simple, theoretical physical principles, yet they are not commonly used in this context. When a physiological concentration of carbon dioxide was present in the tonometer gas our results would have underestimated by approximately 5% without the appropriate correction factor. We have been able to ignore the exchange of oxygen between blood and sample because the carrier gas for the tonometer was air and the headspace also initially contains air. There may however be an effect if blood is not fully saturated with oxygen because uptake of oxygen by blood reduces absolute headspace pressure.

When multiple headspace equilibrations are used, successive measurements lie on an exponential washout curve and all points contribute to its determination. It is simple to calculate the best fit to such a function if the data are assumed to be homoscedastic, that is measurements at each equilibration have equal variances. We experimented with multiple sample transfers and washouts, but it seemed unlikely that our data would be homoscedastic given that blood volume was reduced at each step, and it was not clear how to weight the contribution of each equilibration in the new washout function. We therefore calculate the sample blood-gas coefficient from the results of the second equilibration and use that result with the first measurement to calculate the initial partial pressure of desflurane in the sample.

Although there is a systematic error in our application of this technique, it is small compared with the confidence interval for an individual measurement and it is even possible that equilibrium within the tonometer was incomplete. The important result for an individual sample is the interval about it within which the true value is expected to lie. The confidence interval of 8.5% of the reading for an individual sample may seem disturbingly wide, but it bears comparison with others in the literature. Fink and Morikawa[1] published their much quoted article without any results. Knill and co-workers[2] used their method with 10-ml blood samples tonometered with isoflurane equilibrated four times in syringes. Their duplicate samples agreed within 4.1% (cf. our 8.5%), but they did not test their technique against tonometered blood. Landon and co-workers[3] collected 0.5-ml specimens into 2-ml vials and performed four headspace equilibrations. When they tested this method using blood tonometered with 0.24% isoflurane they found a mean error of less than 1% of the true value and a variability similar to ours in absolute terms, but because we used 1% isoflurane in the tonometer, our variability was less as a proportion of the true value. Dwyer and co-workers[5] performed two headspace equilibrations of 5-ml samples within syringes and found a systematic error of −4±7% (cf. our −2.3±8.5%) when measuring blood equilibrated with isoflurane in a tonometer. Several groups have used a single headspace equilibration to determine the partial pressure of gas within the sample. The headspace measurement is related to initial partial pressure by a nomogram which either relies on an assumed blood-gas coefficient or requires tonometry of a separate blood sample with a known gas mixture. This presents problems if the blood-gas coefficient is variable (e.g. during cardiopulmonary bypass). Frei and co-workers[6] described a technique of single headspace equilibration of 0.5 ml of blood in a 5-ml vial. When measuring isoflurane they obtained a coefficient of variation of 2.8% (c.f. our 4.3%). Their method allows one analyst to process 40 samples per hour using a given nomogram. Flynn and co-workers[7] injected each of five 5-ml vials with 0.6 ml of blood from the same sample, taking the mean value as the result for that sample. They claimed a coefficient of variation of less than 4% for isoflurane, which was less than the error in the slope of their nomogram (1.93±0.11). Katoh and colleagues[8] measured sevoflurane partial pressures in arterial blood from a single headspace equilibration. They measured the blood-gas solubility in each case by obtaining a blood sample before anaesthesia and equilibrating it with a known amount of sevoflurane vapour, but did not validate their technique.

In summary, the two-stage method described in this article allows rapid measurement of the partial pressure of desflurane and blood-gas solubility in a single 2-ml sample of blood with accuracy and repeatability similar to published results on the measurement of isoflurane.

## Modifying infant stress responses to major surgery: spinal *vs* extradural *vs* opioid analgesia

**A. R. Wolf** and E. Thomas*
*Royal Hospital for Sick Children, Bristol and Department of Anaesthesia, Lancaster General Hospital*

In a previous infant study we have shown that extradural analgesia suppresses stress responses to major surgery better than analgesic doses of opioid.[1] Adult work suggests that spinal analgesia may be better than extradurals.[2] We therefore wished to determine if this was true in infants undergoing major surgery.

After appropriate consents, we studied 26 infants undergoing intrabdominal or thoracic surgery. Patients were anaesthetised in a standardized fashion with isoflurane in 30% oxygen. Before surgery, patients were randomized to receive one of three analgesia regimens: Group 1 (n=10) single dose spinal of 0.5% heavy bupivacaine (0.1 ml $kg^{-1}$) plus extradural catheter placement, Group 2 (n=8) extradural analgesia with an initial dose of 1 ml of 0.25% bupivacaine (with additional increments), Group 3 (n=8) i.v. fentanyl (1 $\mu g$ $kg^{-1}$ with additional increments). Additional analgesia (extradural bupivacaine groups 1 and 2, i.v. fentanyl Group 3) was administered if arterial pressure rose 20% above baseline values. Blood samples for glucose and catecholamines were taken after induction, 45 min and at the end of surgery. Heart rate and arterial pressure were recorded at 5-min intervals. Group comparisons for parametric data were made using repeated means analysis (Manova).

Groups were matched for ages and weights. Heart rate increased significantly ($P<0.05$) with the start of surgery in groups 2 and 3, but not Group 1. Systolic arterial pressure in Group 1 decreased from a mean of 94.6 (SD 19 mm Hg) before induction to 76.1 (SD 18.4) after administration of spinal bupivacaine. Plasma glucose concentrations during surgery are shown in figure 1 for the three groups. Repeated measures analysis indicated a significant group effect ($P<0.05$) in the order opioid> extradural>spinal. Adrenaline concentrations rose during surgery in a similar fashion, but failed to achieve statistical significance owing to large interpatient variability and small sample size. Noradrenaline concentrations decreased significantly during surgery in Group 1. This study suggests that spinal anaesthesia may be better than extradural anaesthesia in obtunding cardiovascular and metabolic responses to surgery and highlights the value of routine intraoperative glucose estimations.

## Early clinical evaluation of diaspirin cross-linked haemoglobin in major surgery: a pilot study

N. Snook*, R. Srinivasa* and **M. C. Bellamy**
*Department of Anaesthesia, St James' University Hospital, Leeds*

Diaspirin cross-linked haemoglobin (DCLHb) is a tetramer of chemically crosslinked α subunits of stroma-free haemoglobin. DCLHb carries oxygen. In volunteers it combines a vasopressor effect with a colloid osmotic effect similar to 5% albumin solution DCLHb contains no blood group antigens or cell components.

In this prospective randomized single blind study we enrolled 20 ASA I–II patients undergoing major surgery with an expected blood loss of >1000 ml. Patients were selected randomly to receive either 50 mg $kg^{-1}$ of 10% DCLHb or an equivalent volume of 0.9% NaCl, administered after induction and before surgical incision. Pre- and post-infusion laboratory investigations included FBC, U and E and creatinine, LFT, haptoglobin, haemopexin, free haemoglobin, amylase and antibodies to DCLHb. Haemodynamic data were obtained by invasive monitoring (arterial, CVP) and transthoracic bioimpedance

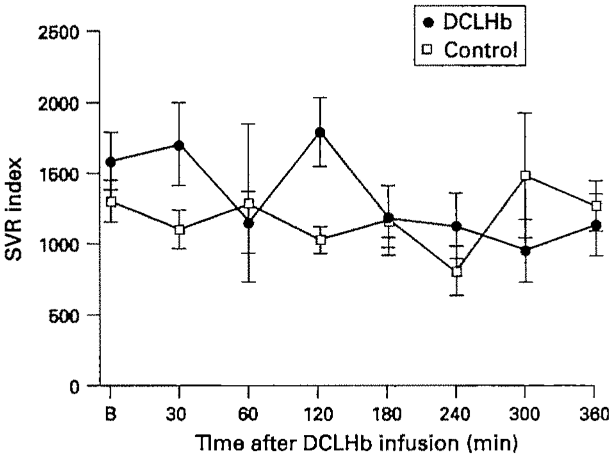

*Figure 2* Changes in systemic vascular resistance (SVR) with time. The MAP difference was correspondingly significant. This difference disappeared after 3 h. AUC: SVRI $P=0.024$

(BOMED) We recorded AP, HR, CO, CVP, $Sp_{O_2}$, urinary output, fluid replacement and transthoracic impedance (thoracic water). Safety end-points were renal failure, myocardial ischaemia and liver dysfunction.

There were no differences in any other haemodynamic or laboratory measurements. There were no outcome differences between groups (fig. 2).

This pilot study shows that DCLHb has short-lived vasopressor effects which may be of physiological value in major surgery. There were no adverse effects on haemodynamic variables or laboratory tests of organ function. A follow-up study to investigate the efficacy of DCLHb in tissue oxygenation and outcome is indicated.

## Effect of different respiratory patterns on respiratory sinus arrhythmia in conscious volunteers

P. A. Glew*, C. J. Pomfrett and J. R. Sneyd
*Department of Anaesthesia, Derriford Hospital Plymouth, and University Department of Anaesthesia, Manchester Royal Infirmary*

Respiratory sinus arrhythmia (RSA) has been proposed as a measure of anaesthetic depth.[1] We have measured RSA and heart rate variability (HRV) in order to test whether substantial alterations in respiratory pattern affected the level of RSA while level of consciousness was unchanged.

Six male volunteers breathed air at tidal volumes of 5 and 10 ml $kg^{-1}$ with I:E ratio of 1:1, 1:2 and 2:1. Breathing was synchronized by an electronic metronome at 45 beat $min^{-1}$. Normocapnia was maintained by the addition of dead space. The six experimental periods of 10 min followed periods of stabilization. Raw ECG was digitised at 1000 Hz using a CED 1401 plus interface and Spike 2.01 software (Cambridge Electronic Design Ltd). ECG was inspected visually to exclude artefact and R waves was detected by templating. Respiration was measured using a flow meter (FDE Magtrak) linked to the interface. RSA was calculated using the method of Pomfrett and colleagues[1] to determine the R statistic. In order to determine independently the level of HRV, power spectral analysis of the ECG was performed by 256 point fast Fourier transformation of the ECG tachygram re-sampled at 4 Hz. The area under the curve of the low frequency (LF) peak (0.08–0.156 Hz) and high frequency (HF) peak (0.218–0.281 Hz for I:E=1:2 and 2:1, 0.328–0.406 for I:E=1:1) were measured. Note that the position of the HF peak varies with respiratory rate.

*Table 1* Mean R, low frequency (LF) are and high frequency (HF) area (SD). Mean R was not significantly altered by changes in tidal volume or I:E ratio, paired *t*-test

| | Mean R (dimensionless) | LF area ($Hz^2 \times 10^{-5}$) | HF area$\times 10^5$ ($Hz^2 \times 10^{-5}$) |
|---|---|---|---|
| 5 ml $kg^{-1}$: | | | |
| I:E 1:1 | 0.179 (0.068) | 5.41 (5.0) | 3.95 (2.4) |
| 1:2 | 0.193 (0.048) | 6.75 (5.4) | 4.44 (2.6) |
| 2:1 | 0.270 (0.013) | 7.23 (5.2) | 3.56 (1.9) |
| 10 ml $kg^{-1}$: | | | |
| I:E 1:1 | 0.197 (0.046) | 6.58 (8.7) | 2.68 (9.8) |
| 1:2 | 0.256 (0.071) | 7.98 (5.2) | 8.72 (7 6) |
| 2:1 | 0.270 (0.012) | 6.87 (6.0) | 5.24 (3.9) |

Substantial changes of tidal volume and I:E ratio failed to alter these measures of RSA in conscious volunteers (table 1). This investigation could be usefully repeated in anaesthetized patients.

## Effect of halothane and sevoflurane on slowly adapting lung receptors in the rabbit

C. Moores*, A. S. Davies* and M. Dallak*
*Department of Anaesthetics, University of Edinburgh*

We compared the effect of halothane and sevoflurane on the discharge frequency of slowly adapting receptors (SARs) in the lungs of rabbits using a single nerve fibre recording technique.

Halothane, enflurane and isoflurane were studied in the past[1] and were found to raise the threshold of firing of lung SARs, while at the same time increasing their discharge frequency above this threshold. No quantitative difference was found between these agents. Sevoflurane has not been studied but is known to be much less irritant to the airways,[2] and therefore its effect on lung receptors may be different from other agents.

Four New Zealand White rabbits were studied. Each received 25% urethane 7 ml $kg^{-1}$, with vecuronium 0.2 mg $kg^{-1}$ and its lungs were ventilated with a tidal volume of 6 ml $kg^{-1}$ at a rate of 80 beat $min^{-1}$ Both vagi were divided and the left was desheathed and repeatedly split into thin filaments from which recordings were made, until a filament was found containing a single nerve fibre arising from a lung SAR. The lungs were then ventilated with oxygen containing sevoflurane or halothane at end-tidal concentrations of 2.0% followed by 5%. A number of receptors from each rabbit were studied. Recordings were made of tidal volume, airway flow and pressure, arterial pressure, heart rate and nerve fibre discharge frequency. Comparisons were made using two-factor repeated measures analysis of variance.

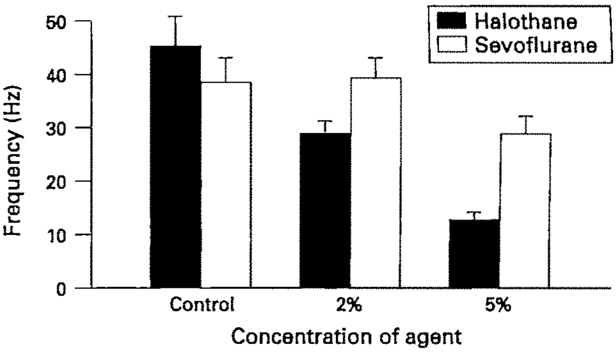

*Figure 3* Discharge frequency during expiration of slowly adapting receptors exposed to volatile agents (mean (SEM)).

Recordings were made from 19 slowly adapting receptors. We found that increasing agent concentration significantly decreased the frequency of discharge of the receptors during expiration ($P<0.0005$) (fig 3). The decrease caused by halothane was significantly larger than that caused by sevoflurane ($P<0.0005$). However, we found no significant effect of either agent on the discharge frequency of the receptors during the final 100 ms of inspiration, when discharge frequency is at a maximum.

## Anaesthetic and sedative agents suppress neutrophil interleukin-8 release

H. F. GALLEY*, A. M. DUBBELS* AND N. R. WEBSTER
*Academic Unit of Anaesthesia and Intensive Care, Institute of Medical Sciences, University of Aberdeen*

Immune suppression is common in postoperative patients and those on intensive care. Trauma and surgical stress modify the immune response. However, anaesthetic and sedative agents also affect some aspects of immune function. Interleukin-8 (IL-8) is a chemotactic and activating factor produced by neutrophils and induces the expression of adhesion molecules, enhancing neutrophil adhesion to the endothelium. We investigated the effect of anaesthetic agents on neutrophil production of IL-8. Isolated human neutrophils were exposed to varying concentrations of propofol or midazolam in the presence of lipopolysaccharide $1.7\ \mu g\ ml^{-1}$. After 20 h, IL-8 was measured in culture supernatants using ELISA. Data were analysed using Kruskal-Wallis analysis of variance.

Both propofol ($P=0.006$) and midazolam ($P=0.05$) suppressed neutrophil IL-8 accumulation at sedative concentrations (fig. 4). Northern analysis revealed increased mRNA for IL-8 at the highest concentrations of both agents. Interaction of released IL-8 with cell surface receptors may affect the appearance of mRNA within the cell and that decreased release of IL-8 in response to anaesthetic agents therefore results in increased mRNA for IL-8. The precise mechanism requires further investigation. Neutrophils themselves augment neutrophil recruitment and activation through local production of IL-8 thus amplifying antimicrobial defence. Suppression of this process by anaesthetic and sedative agents may predispose postoperative and intensive care patients to infection.

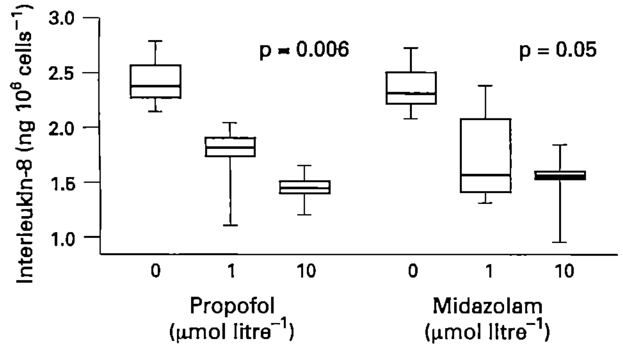

*Figure 4* Effect of propofol/midazolam on lipopolysaccharide-stimulated IL-8 production by neutrophils. Bars are median and 25th and 75th percentiles with range shown as vertical lines. Data were from between 6 and 8 separate experiments.

## Effect of exogenous nitric oxide/superoxide on interleukin-8 from human neutrophils

B. H. CUTHBERTSON*, H. F GALLEY* AND N. R. WEBSTER
*Academic Unit of Anaesthesia and Intensive Care, Institute of Medical Sciences, University of Aberdeen*

Patients with acute inflammatory lung injury are commonly treated with inhaled nitric oxide. Such patients have increased concentrations of the chemotactic/activating factor interleukin-8 (IL-8) in their bronchoalveolar lavage fluid leading to the accumulation of neutrophils. These activated cells produce superoxide and proteases, causing lung damage. There is limited evidence to suggest that nitric oxide donors may regulate IL-8 expression in some cell types. The effects of inhaled nitric oxide on mediators of inflammation in the lung are not known. We investigated the effect of a nitric oxide donor and a combined nitric oxide/superoxide (and hence peroxynitrite) donor on lipopolysaccharide (LPS)-mediated accumulation of IL-8 from cultured human neutrophils.

Cells were isolated using a single step density gradient and incubated with and without LPS for 20 h in the combined presence of a range of concentrations of the combined nitric oxide/superoxide donor 3-morpholinosydnonimine (SIN-1) or the nitric oxide donor, 1,2,3,4-oxatriazolium, 5-amino chloride (GEA-3162). IL-8 was measured in culture supernatants using enzyme immunoassay. IL-8 accumulation from LPS-stimulated neutrophils was significantly and dose-dependently decreased by SIN-1 ($P=00065$, Kruskal-Wallis ANOVA). Basal IL-8 accumulation from unstimulated cells was also decreased by SIN-1 ($P<0.01$, Mann-Whitney $U$ test) (fig. 5). In contrast, GEA-3162 increased IL-8 in both LPS-stimulated ($P=0.02$, Kruskal Wallis) and unstimulated neutrophils ($P<0.02$, Mann-Whitney).

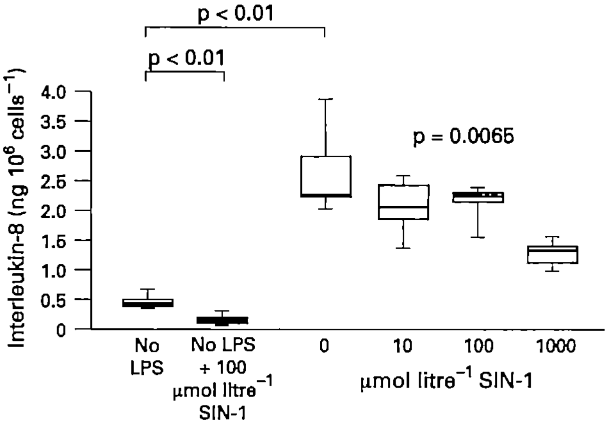

*Figure 5* The effect of SIN-1 on IL-8 accumulation from PS stimulated neutrophils. Plot is median, and 25th and 75th percentiles with range shown as vertical bars. Data are from six experiments.

Nitric oxide and superoxide have profound effects on IL-8. The transcription factor NFκB regulates IL-8 expression. Nitric oxide has been shown to activate NFκB in some cell types, but acts as an inhibitor in other cells. The effect of peroxynitrite on NFκB is not known. Selective down-regulation of IL-8 within the lung is likely to reduce neutrophil accumulation and may be beneficial. These results may have implications for the treatment of patients with acute lung injury with inhaled nitric oxide.

## Adhesion molecule concentrations in arterial and jugular venous serum after acute brain injury

E. G. MCKEATING*, L. MASCIA AND P. J. D. ANDREWS
*Departments of Anaesthesia and Clinical Neurosciences, University of Edinburgh and Department of Anaesthesia, University of Bari, Italy*

Induction of pro-inflammatory cascades after acute brain injury, with infiltration of leucocytes into brain tissue, results in secondary damage. Adhesion molecules, which are expressed on the surface of leucocytes and endothelial cells, have an important role in the migration of leucocytes into tissue after injury. L-selectin is believed to control light adhesion of leucocytes to the endothelium, whereas intercellular adhesion molecule-1 (ICAM-1) mediates later firm attachment. We hypothesized that an upregulation of ICAM-1 and L-selectin expression after acute brain injury would result in elevated serum concentrations of these molecules, with jugular venous concentrations being greater than arterial.

We investigated arterial and jugular venous (JV) concentrations of soluble ICAM-1 and soluble L-selectin, in 32 patients (22 with traumatic brain injury and 10 with spontaneous subarachnoid haemorrhage) admitted to the intensive care unit (ICU). Paired arterial and JV blood samples were taken at designated times after

*Table 2* Mean arterial concentrations at difference times

| | ICAM-1 (ng mg$^{-1}$) | | | L-selectin (ng ml$^{-1}$) | | |
|---|---|---|---|---|---|---|
| Time | Mean | 95% CI | *P* value* | Mean | 95% CI | *P* value* |
| Control | 254 | 217–290 | | 904 | 814–994 | |
| Admission | 272 | 223–322 | 0.532 | 625 | 565–685 | <0.0001 |
| 24 h | 273 | 235–313 | 0.436 | 573 | 529–616 | <0.0001 |
| 48 h | 316 | 267–365 | 0.040 | 591 | 536–645 | <0.0001 |
| 96 h | 448 | 339–557 | 0.002 | 569 | 505–634 | <0.0001 |

*Two tailed *t*-test, patient samples *vs* control. Control samples are venous.

brain injury: on admission, at 24 h, 48 h and 96 h. Analysis of serum for L-selectin and ICAM-1 was performed by ELISA. A total of 220 samples (110 pairs) were analysed in duplicate for each adhesion molecule. Serum samples were taken from 12 apparently healthy volunteers to be used as controls.

Median time from primary insult to admission sample was 8 h 30 min (range 2–14 h). Median age was 37 (range 17–69) yr. Median Glasgow Coma Score was 7 (range 3–15).

For ICAM-1, mean arterial concentration at each of the time points after injury is shown in table 2 (ANOVA, $P<0.001$), with the concentration at 96 h being significantly higher than at the other time points ($P=0.001$, $P<0.001$, $P=0.014$ respectively). Mean JV-arterial difference was 6.9 ng ml$^{-1}$ (95% CI [−4.5–18.3], $P=0.31$). For L-selectin, mean arterial concentrations are shown in table 2 (ANOVA $P=0.40$). Mean JV-arterial difference was 3.6 ng ml$^{-1}$ (95% CI [−8.0–15.2], $P=0.60$).

We have found serum concentrations of ICAM-1 to be elevated at 48 h after acute brain injury, and to be elevated further at 96 h. This is in contrast with an unexpected decrease in serum L-selectin from normal values from the time of admission. No differences between jugular venous and arterial concentrations were found. Increased serum concentrations of soluble ICAM-1 have been reported in many inflammatory disease states including septic shock[1] and bacterial meningitis. Elevated serum concentrations of L-selectin have also been reported in sepsis and cerebral malaria A recent study[2] also reported a decrease in serum concentrations of L-selectin in adult respiratory distress syndrome. this may be a result of sequestration of L-selectin by activated endothelium. Although the cerebral vasculature is structurally different from the systemic vasculature, the pathophysiology of the inflammatory process after a primary insult may be similar.

## Effect of local anaesthetic agents on *in vitro* proliferation of human dermal fibroblasts

G. R. Masterson*, G. S. Ashcroft* and J. M. Hunter
*University Department of Anaesthesia, Liverpool and Cells, Immunology and Development, University of Manchester*

Local anaesthetic agents are commonly infiltrated into the skin to produce per- or postoperative analgesia. Although fibroblasts are known to play pivotal roles in cutaneous wound healing and scarring, there have been few studies of how local anaesthetic agents influence dermal fibroblast proliferation. One study concluded that lignocaine and ropivacaine inhibit *in vitro* fibroblast proliferation in a dose-dependent manner.[1] It is recognized that age, sex and health status are important determinants of fibroblast behaviour, but most human fibroblast studies performed *in vitro* on donor specimens have failed to control for these variables.[2] This study assessed, first, the influence of donor age and, second, the differences between lignocaine and bupivacaine, on *in vitro* proliferative capability of dermal fibroblasts after exposure to clinically relevant concentrations of both agents.

*Table 3* Mean (SD) proliferation of human dermal fibroblasts when cultured in different concentrations of local anaesthetic agent as measured by $^3$H-thymidine incorporation, expressed as % counts min$^{-1}$ of control. *$P<0.05$ when old compared with young for same concentration of lignocaine or bupivacaine; †$P<0.05$ when equimolar concentrations of bupivacaine and lignocaine are compared within same age group

| | Young | Old |
|---|---|---|
| Lignocaine 1 μmol litre$^{-1}$ | 77 (17.1) | 22 (8.5)* |
| Lignocaine 10 μmol litre$^{-1}$ | 61 (10.7) | 14 (5.2)* |
| Lignocaine 100 μmol litre$^{-1}$ | 54 (14.5) | 9 (3.4)* |
| Bupivacaine 1 μmol litre$^{-1}$ | 98 (14.9) | 55 (13.8) |
| Bupivacaine 10 μmol litre$^{-1}$ | 77 (10.4) | 33 (8.4)*† |
| Bupivacaine 100 μmol litre$^{-1}$ | 61 (15.5) | 21 (6.6)*† |

Primary cultures of human dermal fibroblasts were obtained from explant cultures of dermis excised from the inner aspect of the upper arm of five young (20–30 yr) and 5 old (60–70 yr) healthy male volunteers. The cells were cultured in Dulbecco's modified Eagle's medium containing 10% fetal calf serum and antibiotics at 37 °C, and used for experiment after four to six passages of cell growth. The cells were seeded in 96-well plates (2×10$^4$/well) and allowed to attach for 24 h before 12 h of serum starvation. The fibroblasts were then exposed to lignocaine or bupivacaine, diluted in serum-free medium to concentrations of 1, 10 or 100 μmol litre$^{-1}$, for 4 h. $^3$H-thymidine was added to produce a final concentration of 0.5 μCi ml$^{-1}$. After 24 h, the cells were rinsed and the radioactivity was measured using a liquid scintillation counter. The studies were repeated in triplicate. Student's *t*-test (unpaired or paired) was used for statistical analysis of the data.

Fibroblast viability was not affected by any of the local anaesthetic concentrations used. Both lignocaine and bupivacaine inhibited fibroblast proliferation in a dose-dependent manner. At each concentration of local anaesthetic agent, inhibition of fibroblast proliferation was significantly greater for those donated from old subjects compared with those from young subjects. For fibroblasts from young subjects, there was no significant difference in proliferation after exposure to equimolar concentrations of lignocaine or bupivacaine. However, in fibroblasts from old subjects, there was significantly greater inhibition of proliferation with lignocaine compared with equimolar concentrations of bupivacaine.

After *in vitro* exposure to clinically relevant concentrations of lignocaine or bupivacaine, inhibition of proliferation is greater for fibroblasts donated from old subjects compared with those from young subjects (table 3). In equimolar concentrations, lignocaine inhibited proliferation of fibroblasts from old subjects more than bupivacaine. However, there was no difference between the two agents in inhibition of proliferation for fibroblasts from the young. This study only describes changes in fibroblast numbers and does not indicate changes in fibroblast function.

## Nested case–control study of risk factors for cardiovascular death after anaesthesia and surgery

S. J. Howell, Y. M. Sear, D. Yeates, M. Goldacre, J. W. Sear and P. Foex
*Nuffield Department of Anaesthetics, Radcliffe Infirmary, Oxford and Unit of Health-Care Epidemiology, Oxford*

We report a case-control study of risk factors for cardiovascular death after anaesthesia and surgery. This study was nested within the Oxford Record Linkage study (ORLS). This is a large epidemiological study which collects data on all hospital care delivered within the area previously encompassed by the Oxfordshire Regional Health Authority.

Patients undergoing elective surgery under general anaesthesia in five hospitals within the ORLS between 1979 and 1990 constituted the study population. The ORLS was interrogated to identify patients aged over 18 yr who died within 30 days of surgery, and who had a cardiovascular cause of death recorded on their death certificate (ICD9 codes 401 to 438 inclusive, but excluding 415.1 which is pulmonary embolism). Patients undergoing cardiac and neurosurgery were excluded. For each case a control patient matched on age, sex, type of surgery and consultant was identified. As required by the local Ethics Committee, consent was obtained from the consultant in charge of each patient's care for the ORLS to identify individual patients, and for the medical records of these patients to be examined. Data on cardiovascular risk factors and history of cardiovascular disease were collected from the medical records of each patient. The associations between various potential risk factors and postoperative cardiovascular death were examined using conditional logistic regression.

One hundred and ten case-control pairs were identified; 70 (64%) of the cases were male. the mean age of the cases was 72.0 (SD 19.55) yr and that of the controls was 71.0 (SD 10.26) yr. The final regression model is summarized in table 4.

*Table 4* Results of conditional logistic regression analysis

| | Odds ratio (95% confidence limits) | z (Wald test) | *P* value |
|---|---|---|---|
| Hypertension | 2.29 (1.17–4.50) | 2.41 | 0.016 |
| Myocardial infarction | 3.63 (0.94–4.50) | 1.87 | 0.062 |
| Heart failure | 2.15 (0.81–5.72) | 1.54 | 0.13 |
| Cerebrovascular accident | 1.73 (0.53–5.69) | 0.90 | 0.37 |
| Angina | 1.17 (0.39–4.30) | 0.24 | 0.81 |

Only the effect of hypertension reached significance at the conventional 5% level, although the data also give support for an effect of previous myocardial infarction.

## Randomized trial of hypotensive anaesthesia on cardiac, renal and cognitive outcome after total hip replacement

**N. E. SHARROCK***, P. WILLIAMS-RUSSO*, M. E. CHARLTON* AND E. P. SZATROWSKI*
*Departments of Anaesthesiology and Medicine, The Hospital for Special Surgery, New York, USA*

The use of hypotensive anaesthesia in elderly high-risk patients is controversial owing to the perceived risks of stroke, myocardial infarction or renal dysfunction. This is a study of hypotensive extradural anaesthesia in elderly high-risk patients.

Following institutional review board approval, 235 patients gave informed consent to receive either hypotensive or normotensive extradural anaesthesia (mean arterial pressure (MAP) 50 mm Hg *vs* 65 mm Hg) throughout surgery. The study design was randomized and double-blinded, as people collecting postoperative data were not aware of the patients' treatment group. Entry criteria were 70 yr of age or older, or 60 yr of age or older with a history of either hypertension or ischaemic heart disease. All patients had a preoperative assessment which included a battery of 10 cognitive function tests[1] which were repeated 6 months after operation. After surgery, renal function and myocardial ischaemia/infarction were screened using predefined criteria.

Myocardial infarction or ischaemia occurred in 6% in the low MAP group and 4% in the higher MAP groups. Corresponding rates for renal dysfunction were 0.85% and 4%, respectively. Long-term cognitive disturbances were 5% and 11% in the low and higher MAP groups, respectively. Five percent of patients required homologous blood transfusion in the low MAP group, and about 6% in the higher MAP group. None of these differences were significant.

Hypotensive extradural anaesthesia, as used in this study, does not increase the rate of renal function, cardiac or cognitive complications in elderly high-risk patients.

**Key words**
Anaesthesia, hypotensive. Outcome, cardiac. Outcome, renal. Outcome, cognitive.

## Audit of patients' attitudes to consent to clinical trials in anaesthesia

**J. E. MONTGOMERY*** AND J. R. SNEYD
*Department of Anaesthesia, Derriford Hospital, Plymouth*

Every patient has a right to determine what treatment he or she should receive. When an intervention may not directly benefit the patient, as in clinical trials, informed, freely given consent is all the more important. Over a period of 2 years, 204 patients consented to inclusion in one of six clinical trials in anaesthesia. One of three doctors explained the trial to them and left an information sheet which stated that participation was voluntary, their other treatment would not be affected and that they could change their minds at any time. Three were drug company-sponsored multi-centred trials ($n=44$) and had a three-page information sheet, the others were "in-hospital" trials ($n=160$) and the information sheet was one side of A4. We have audited patient satisfaction with the way they were approached and the information they were given.

The text of the information sheets was scored for readability using Flesch reading ease and Flesch-Kincaid grade level (Microsoft Word version 6.0.1). All the patients were sent a questionnaire with a covering letter. If no reply was received after 4 weeks a further letter and questionnaire were sent.

Readability scores of the in-house and the sponsored trial information sheets were similar. We received 158 (77%) completed replies, we were unable to find a current address for 12 (6%) and two patients declined to complete the questionnaire.

There were no significant differences in responses between the in-house and sponsored trial patients (Fisher's exact test). Twenty nine (14%) did not remember seeing an information sheet; of those that did 99% felt it was easy to read and understand and 94% felt it was an accurate description of what happened to them.

Five patients said that they had felt pressurized to take part. Three said that this was because they had been approached in a stressful situation before major surgery, one had a brother who died under anaesthesia but felt that she should take part to help other people and the last made no comment but did state later in the questionnaire that she felt her treatment had been improved by taking part in the trial.

Although most (154 (97%)) were aware that participation was entirely voluntary and that their treatment would not be affected by their decision only 131 (83%) were aware that they could change their minds at any time after giving consent. When asked if they would have liked to have been warned about the trial before coming into hospital 64 (41%) would have, 80 (51%) would not and 14 (8%) were unsure.

In conclusion, patient satisfaction with the consent process was not improved by increasing the volume of information given. We have shown that patients do not always have good recall for information given to them while in hospital but in general our patients were happy with the way they were approached and the information given. As anaesthetists involved in research it is very difficult to see prospective patients other than immediately before surgery and inevitably some people will find this a stressful time and will not be receptive to other interventions.

## Point mutation in the channel lumen of a GABA$_A$ receptor regulates modulation by isoflurane

**M. D. Edwards**, R. M. Jones and G. Lees
*Department of Anaesthetics, St Mary's Hospital Medical School, Imperial College of Science, Technology and Medicine, London*

GABA is the most important inhibitory transmitter in the mammalian brain and the pentameric GABA$_A$ receptor/chloride channel is an acknowledged target for a broad range of anaesthetic drugs.[1] We recently described the upregulation of GABA activated chloride currents through the *Drosophila* RDL receptor and its ion channel mutant (which is insensitive to picrotoxinin) by clinical concentrations of isoflurane.[2] In this study we have examined the dose-dependence of anaesthetic interaction with both wild-type (WT) and mutant (MUT: bearing a point mutation in the M2 domain) RDL channels.

cDNA samples (Cornell University) were transcribed *in vitro*, then expressed in *Xenopus* oocytes using established techniques.[2] Ion channels were examined 1 to 2 days later using two-electrode voltage-clamp. GABA was applied for 5–15 s by throughput perfusion (around 10 ml min$^{-1}$). Concentration-response curves were plotted by a point-to-point fit before and after equilibration with isoflurane. Statistical assessment was by two-tailed Student's *t*-test, where appropriate. All reported observations are based on a minimum of three replicated experiments.

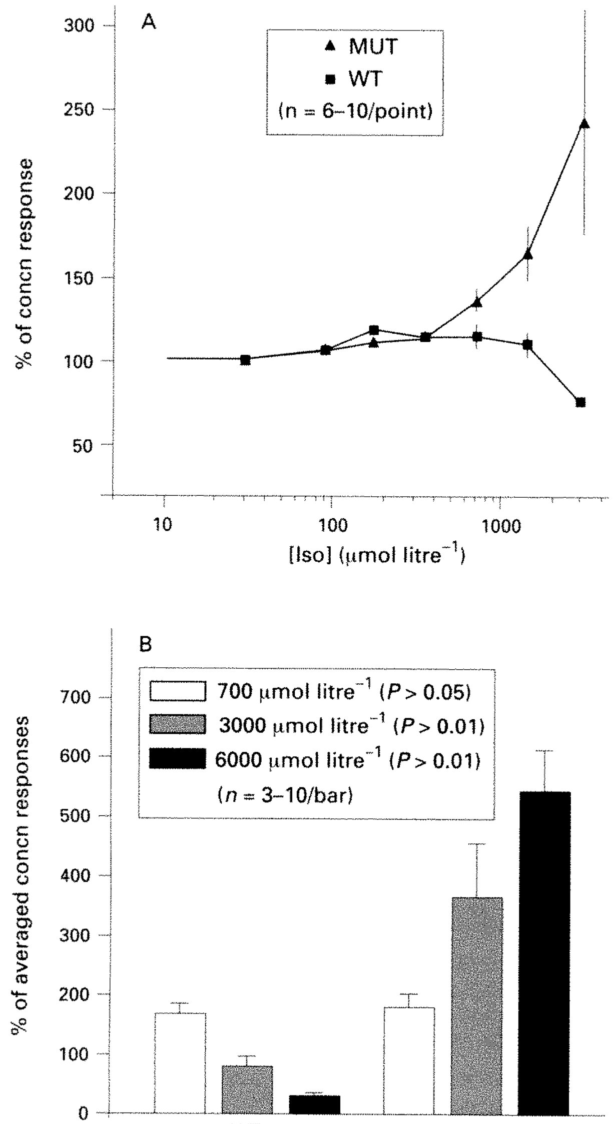

*Figure 6* Dose-dependent effects of isoflurane on GABA-evoked responses. (Bars represent SEM.)

Preliminary studies indicated that isoflurane (350–700 μmol litre$^{-1}$) enhanced subsaturating GABA-induced conductances: equilibrium was attained within 5 min of onset and responses reversed within 10 min of washout ($n$=6). The effect of varying concentrations of isoflurane, over the range 30–3000 μmol litre$^{-1}$, was examined on both receptor isoforms at a fixed GABA concentration (EC$_{25}$: 5.62 μmol litre$^{-1}$). Both isoforms of the receptor were weakly upregulated by anaesthetic 175–700 μmol litre$^{-1}$. However, at concentrations of 1–3 mmol litre$^{-1}$, a drastic divergence in modulatory effect was evident: WT receptor conductances resulted in bell-shaped curves due to dose-dependent depression by isoflurane, whereas MUT responses were dose-dependently enhanced across this range (fig. 6A). These observations were extended across a wide concentration range (fig. 6B) in independent experiments: at 6 mmol litre$^{-1}$, WT responses were depressed about five-fold while MUT conductances were potentiated to a similar degree and showed no tendency to saturate. To seek a mechanism for the divergent modulation, desensitization kinetics for the two isoforms were characterized. Neither WT or MUT receptors desensitized significantly ($P$>0.05, $n$=5–7) in response to a 3-min challenge with saturating GABA 2 mmol litre$^{-1}$ in the absence or in the presence of isoflurane 6 mmol litre$^{-1}$.

At concentrations in the clinical range (0.1–0.7 mmol litre$^{-1}$) isoflurane weakly (<2-fold) upregulated currents through both receptor isoforms. Low affinity responses to the anaesthetic were qualitatively divergent for WT and MUT channels, which were both demonstrably non-desensitizing. A point mutation in the receptor protein clearly impinges on the anaesthetic pharmacology in the invariant lipid environment of the oocyte membrane. This reinforces suggestions that isoflurane interacts directly with channel forming proteins and highlights the putative involvement of the M2 channel domain, in anaesthetic recognition, by the ligand-gated receptor superfamily.[3]

## Action of isoflurane at GABA$_A$ receptors: effect of intracellular calcium and diffusible cytoplasmic messengers

**N. D. Foden***, G. Lees and R. M. Jones
*Department of Academic Anaesthetics, Imperial College School of Medicine at St Mary's, London*

The GABA$_A$ receptor is a sensitive target for anaesthetics,[1] the channel proteins may be modulated directly[1] or as a consequence of changes in cytoplasmic messengers[2] or free intracellular calcium ([Ca$^{2+}$]$_i$).[3]

Primary cultures of rat cortex were grown in neurobasal media with B27 serum replacement (Sigma). Two patch conformations were used—non-invasive amphoteracin perforated recording ($n$=6) was compared with whole-cell patch clamp which facilitates loss of diffusible macromolecules from the cytoplasm.

Potassium gluconate-based intracellular solutions which contained BAPTA 12 mmol litre$^{-1}$ ($n$=6) or EGTA 1.25 mmol litre$^{-1}$ ($n$=5) calculated to buffer [Ca$^{2+}$]$_i$ to 5 nmol litre$^{-1}$, or 330 nmol litre$^{-1}$, respectively. GABA concentration response curves were fit to a three-term logistic equation before, during and after

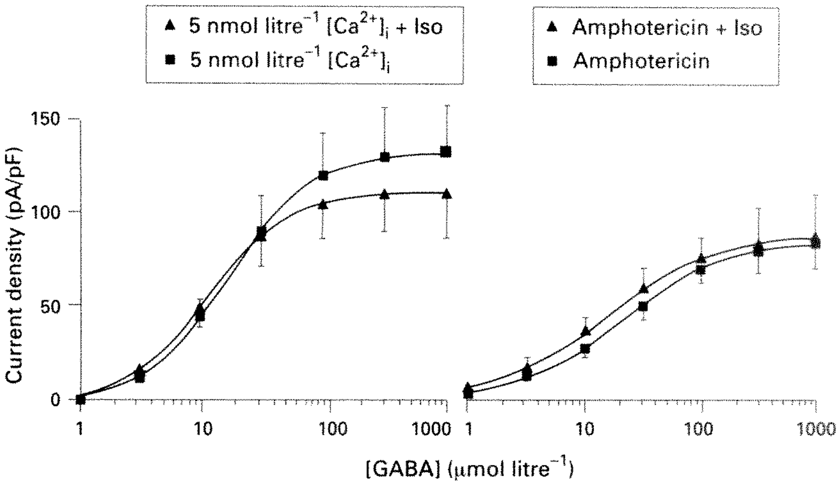

*Figure 7* GABA concentration response curves and the effect of isoflurane (means (SEM)).

the application of isoflurane 320 μmol litre$^{-1}$ (the control curve being taken as the mean of the pre- and post-isoflurane response).

Results were normalized for cellular capacitance to compensate for cell size. The effect of isoflurane on individual cells was analysed by paired *t*-test, a one-tailed test being used for the predicted reduction in $EC_{20}$. Comparison of isoflurane effect between groups was made by one-way analysis of variance.

Figure 7 shows the effect of isoflurane on the cells in the perforated patch group and whole cell ([Ca$^{2+}$]$_i$ 5 nmol litre$^{-1}$) group. In acute experiments, the response to high concentrations of GABA was equally depressed by isoflurane in the whole cell and perforated patch conformation. In all conformations isoflurane induced a significant ($P<0.05$) reduction of the GABA $EC_{20}$. No significant difference ($P>0.05$) in potency ratio or maximal GABA response depression was seen between groups.

Isoflurane enhanced the affinity of GABA for its receptor and upregulated chloride currents at subsaturating agonist concentrations regardless of the intracellular milieu. Diffusible messengers do not regulate anaesthetic-induced modulation or desensitization at high GABA concentrations.

## Effects of NMDA antagonists and thiopentone on glutamate release from rat cerebrocortical slices

B. NICOL, D. J. ROWBOTHAM AND D. G. LAMBERT
*University Department of Anaesthesia, Leicester Royal Infirmary, Leicester*

There are several reports to suggest that i.v. anaesthetic agents interfere with the release of glutamate.[1 2] In a previous study we have shown that thiopentone and ketamine did not affect the re-uptake of this neurotransmitter.[3] We have therefore examined the effects of these agents on K$^+$ (46 nmol litre$^{-1}$) evoked release of glutamate from rat cerebrocortical slices.

Cerebrocortical slices 350 μm thick were prepared from female Wistar rats (200–250 g). Immediately after suspension in oxygenated (95% oxygen, 5% carbon dioxide) Krebs buffer pH 7.4, the slices were pipetted into a perfusion chamber constructed from the barrel of a 2-ml syringe. Glass wool was packed into the needle end to retain the slices and a flow diffuser inserted. Slices were perfused at 1 ml min$^{-1}$ in Krebs buffer for 1 h, after which 2-ml fractions were collected for 6 min, before a 2 min pulse of 46 mmol litre$^{-1}$ K$^+$ ($S_1$). Slices were perfused for a further 30 min, before the second pulse of K$^+$ ($S_2$). Ketamine, thiopentone 3–330 μmol litre$^{-1}$ and MK-801 1 μmol litre$^{-1}$, used as an internal positive control were applied for 30 min between $S_1$ and $S_2$. Glutamate concentrations were measured fluorimetrically based on the conversion of NADP$^+$ to NADPH by glutamate dehydrogenase. From the area under the stimulation profiles, the $S_2/S_1$ ratios and the percentage inhibitions were calculated. Data are mean (SEM) for $n=5$–8, and were analysed by Wilcoxon rank sum test.

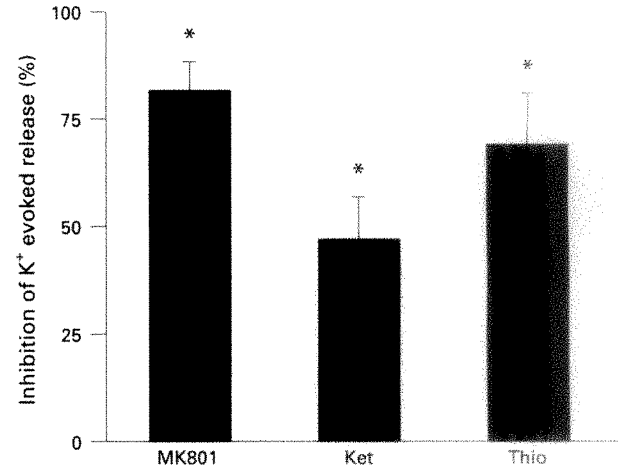

*Figure 8* MK-801 1 μmol litre$^{-1}$, ketamine (Ket, 30 μmol litre$^{-1}$) and thiopentone (Thio, 30 μmol litre$^{-1}$) inhibit K$^+$ evoked glutamate release. $^*P<0.05$ compared with paired control.

Thiopentone and ketamine produced a dose-dependent inhibition of K$^+$-evoked glutamate release, with an estimated $IC_{50}$ of around 10 μmol litre$^{-1}$. MK-801 at 1 μmol litre$^{-1}$ also inhibited release (fig. 8).

These data confirmed the inhibitory effects of MK-801 and ketamine on glutamate release, that presumably resulted from NMDA receptor block. The site(s) of action for thiopentone will require further investigation.

## Target-controlled infusion of Org 21465, a new anaesthetic steroid

**D. Harris***, J. R. Sneyd, P. A. Taylor*, M. Cross*, H. Dale*, P. Vijn*, G. Voortman* and P. Boen*
*Department of Anaesthesia, Derriford Hospital, Plymouth and Phase I Clinical Trials Unit, Plymouth and Organon Teknika NV, Turnhout, Belgium*

Org 21465 is a water-soluble steroidal i.v. anaesthetic. In a previous study, infusion of 1.0–1.8 mg $kg^{-1}$ over 1 min induced anaesthesia in volunteers.[1]

Six healthy male volunteers aged 22–30 yr weighing 63–82 kg each received a 45-min infusion of Org 21465. The rate of infusion was computer-controlled by a pharmacokinetic model driven infusion programme using pharmacokinetic data from the previous study.[1] The infusion programme was set to give three consecutive 15-min periods with stable plasma concentrations of 0.5, 1 and 2 $\mu g\ ml^{-1}$.

After cannulation, subjects rested quietly and received supplementary oxygen by a nasal cannula. Direct arterial pressure, oxygen saturation, ECG, bio-impedance cardiac output, and EEG (high resolution, 7 channels) were monitored continuously. Arterial samples were collected for pharmacokinetic analysis. Org 21465 was infused through a central venous catheter passed from the antecubital fossa.

All subjects were sedated at the lowest target concentration and anaesthetized at the highest. Measured concentrations of Org 21465 were stable during the three 15-min 'steps' and the concentration data from individual subjects were tightly grouped. Measured concentrations were higher than predicted (fig. 9). Heart rate increased progressively at the highest drug concentration. Systolic arterial pressure decreased slightly. All subjects developed excitatory movements, EEG showed dose-related depression without excitation.

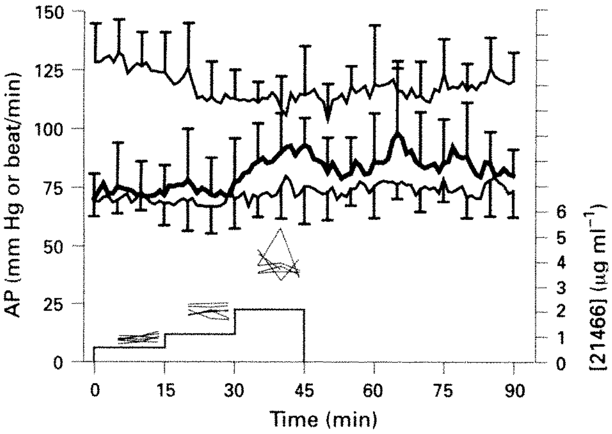

*Figure 9* Systolic and diastolic arterial pressure and heart rate (middle line), mean (SD), before during and after a computer controlled infusion of Org 21465. Measured plasma concentrations in individual patients (thin lines) were higher than predicted (thick line).

Infusion of Org 21465 can produce sedation or anaesthesia. Excitation appears to be dose related, greatest at higher plasma drug concentrations and is probably of subcortical origin. The pharmacokinetics of Org 21465 require further analysis.

## Can enoximone trigger malignant hyperthermia?

**S. M. Enright**, F. R. Ellis, P. J. Halsall* and P. M. Hopkins
*Academic Unit of Anaesthesia, St James's Hospital, Leeds*

It has been suggested that enoximone may trigger malignant hyperthermia (MH), and should be avoided in susceptible (MHS) individuals.[1 2] We therefore studied the effect of enoximone on isolated muscle strips from MHS patients and the effect on subsequent *in vitro* contracture testing (IVCT).

We studied 21 patients who were referred for MH screening (11 MHS, 10 normal). Muscle biopsy and IVCT was performed according to the European MH Group protocol.[3] Halothane contracture tests were repeated on additional muscle strips that had been exposed to enoximone (preservative free) 10 $\mu mol\ litre^{-1}$ for 10 min. All tests were performed within 5 h of biopsy. We observed any changes in tension of the strips after enoximone exposure and whether enoximone altered the contracture response to halothane. We compared changes in maximum tension during IVCT with/without enoximone using Wilcoxon's matched pairs signed rank test.

There was no increase in tension in MHS or normal muscle after exposure to enoximone alone. Neither did any normal muscle strip develop a contracture when halothane was added in the presence of enoximone. Enoximone did not significantly affect the maximum response to halothane in MHS muscle ($P=0.56$, power >80% to detect a difference of ≥1 g) (fig. 10).

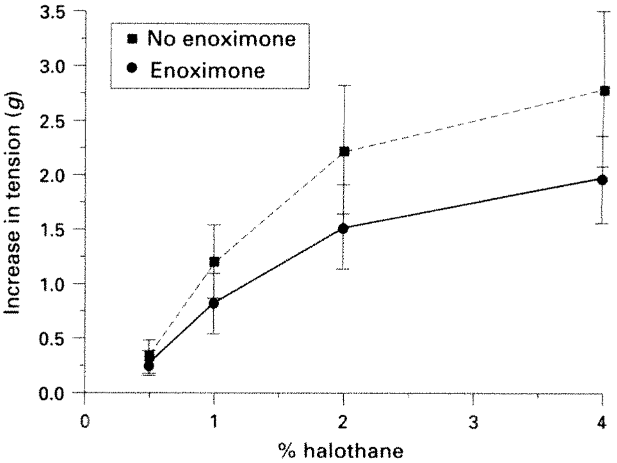

*Figure 10* Effect of enoximone on halothane-induced contracture of muscle from MHS patients (mean (SEM), $n=11$).

The concentration of enoximone used in this study exceeds the maximum plasma concentration achieved therapeutically. It is unlikely that therapeutic concentrations of enoximone will trigger MH or increase response to volatile anaesthetics.

**Key words**

### Cardiovascular changes following administration of remifentanil in combination with either propofol or isoflurane

R. Wroth*, J. Peacock, C. S. Reilly, D. J. Rowbotham and R. Jones
*University Departments of Anaesthetics, Sheffield, Leicester and St Mary's Hospital, London*

The traditional method of presenting cardiovascular data has been to use repeat measures ANOVA for changes with time within a group and multiple individual tests to compare between groups at time points. We present the use of the mean absolute deviation (MAD) score as a measure of cardiovascular variability. Similar techniques have been used to assess variability of infusion systems.[1]

The present data are part of a multicentre study designed to compare responses following remifentanil as part of an inhalation technique with isoflurane, or as part of a total i.v. technique with propofol.

A total of 233 ASA I or II adult patients undergoing surgery anticipated to last at least 30 min were recruited. The patients were unpremedicated and at commencement of anaesthesia received a pre-induction bolus of remifentanil 1 $\mu g\ kg^{-1}$ together with an infusion commenced at 0.5 $\mu g\ kg^{-1}\ min^{-1}$. Anaesthesia was induced with propofol and after neuromuscular block the trachea was intubated. Patients were randomized to receive (a) TIVA, with propofol 9 $mg\ kg^{-1}\ h^{-1}$ reduced to 6 $mg\ kg^{-1}\ h^{-1}$ after 10 min or (b) isoflurane to an end-tidal concentration of 0.6%. The remifentanil infusion was reduced to 0.25 $\mu g\ kg^{-1}\ min^{-1}$ 5 min after intubation. All patients were ventilated to normocapnia with oxygen-enriched air. Non-invasive arterial pressure and pulse were recorded before induction, at loss of consciousness, before and after intubation, before and after skin incision and at 5-min intervals thereafter.

Systolic arterial pressures (SAP) were compared between groups (Student's *t*-test). Variability of systolic spherical pressure in each patient was represented by the MAD score. The mean SAP was calculated for each patient and the absolute difference of each recorded SAP from this mean was determined. The MAD score for each patient was the mean of these differences.

There was no statistical difference between the groups with respect to age, sex or weight. The mean induction dose of propofol was 1.44 (0.64) for TIVA *vs* 1.46 (0.58) $mg\ kg^{-1}$ for isoflurane. The cardiovascular responses to intubation and skin incision are shown in table 5.

*Table 5* Mean systolic arterial pressures (SD). $^*P<0.05$ between groups

| Systolic arterial pressure (mm Hg) | Isoflurane | Propofol |
|---|---|---|
| Before induction | 133 (17) | 134 (17) |
| After induction | 122 (23) | 125 (23) |
| 5 min after intubation | 95 (19) | 100 (17) |
| 5 min after skin incision | 97 (14) | 101 (17)* |
| MAD score, mean (SEM) | 9.0 (0.4) | 8.9 (0.4) |

When remifentanil was used with propofol or isoflurane there was a reduction in systolic arterial pressure with time in both groups. There was no significant difference between the groups in cardiovascular responses to induction or intubation; however, there was a statistical difference after skin incision. There were no significant differences between the groups in cardiovascular variability as calculated by MAD scores.

### Recovery after induction and maintenance of anaesthesia with sevoflurane/oxygen in adult outpatients. A comparison with propofol/sevoflurane/oxygen

R. Gopinath*, J. M. Murray, J. P. H. Fee
*Departments of Anaesthesia, The Ulster Hospital and The Queen's University of Belfast*

The pharmacokinetic profile of sevoflurane parallels that of propofol.[1] The drug possesses a pleasant smell with little or no respiratory tract irritation. We have used sevoflurane alone for induction and maintenance of anaesthesia and compared patient recovery characteristics with those when propofol was used for induction and sevoflurane for maintenance.

After local Ethics Committee approval, 40 adult patients (ASA I and II), aged 18–60 yr, presenting for body surface surgery on a day-care basis were studied. No premedication was used. Patients were allocated randomly to receive either sevoflurane for both induction (using a vital capacity breath technique) and maintenance of anaesthesia (group 1; $n=20$) or propofol for induction followed by sevoflurane for maintenance (group 2; $n=20$). In group 1, inspired sevoflurane was administered in oxygen-enriched air ($F_{IO_2}=0.4$) at an inspired concentration of 8%. Loss of the eyelash reflex was taken as the end point of induction. The time taken and the number of breaths to this point was noted. In group 2, propofol was administered in a dose sufficient to abolish the eyelash reflex and the time to achieve this was noted. After induction, patients in both groups breathed oxygen and air ($F_{IO_2}=0.4$) and sevoflurane (2–3% end-tidal) through a laryngeal mask using a standard breathing system with a fresh gas flow of 5 litre $min^{-1}$. Analgesia, when required, was provided by non-steroidal anti-inflammatory drugs (NSAID) or appropriate local blocks. The duration of anaesthesia was noted. Recovery was assessed by the times to eye-opening on command, to giving correct first name and date of birth and to sitting up unaided. Statistical analyses of the data were performed using ANOVA or Student's *t*-testing; a *P* value of <0.05 was significant.

The mean times taken for induction of anaesthesia and end-tidal concentrations of sevoflurane were similar in both groups. Patients in group 1 opened their eyes, were able to state their first name and date of birth and sat up sooner than those in group 2 (table 6).

*Table 6* Induction times, duration of anaesthesia and recovery characteristics. Data are mean (SD). $^*P=0.0001$; $^{**}P=0.0006$

| | Group 1 | Group 2 |
|---|---|---|
| Induction time (s) | 44 (26) | 40 (8) |
| Eye opening (min) | 6.3 (2.0)* | 9.5 (2.70) |
| First name (min) | 6.5 (2.0)* | 9.8 (2.7) |
| Date of birth (min) | 6.8 (1.9)* | 9.9 (2.6) |
| Sit-up (min) | 7.4 (2.1)** | 10.9 (3.7) |
| $F'_E$ sevofluane (%) | 2.8 (0.4) | 2.8 (0.3) |
| Duration of anaesthesia (min) | 15.8 (8.0) | 15.3 (10.1) |
| No. of breaths | 6.1 (1.2) | – |

We concluded that sevoflurane was an acceptable alternative to propofol for induction of anaesthesia and provides excellent recovery when used as a single agent.

### Effect site modelling of combined fentanyl bolus and alfentanil infusion

A. R. A. Rushton* and J. R. Sneyd
*Department of Anaesthesia, Derriford Hospital, Plymouth*

We have used computer modelling to investigate the potential for saving an expensive infused narcotic, alfentanil, by pre-treatment with a bolus of a longer-acting and cheaper drug, fentanyl. The effect compartment kinetics of fentanyl and alfentanil have been estimated from the hysteresis between plasma concentration and the 95% spectral edge of the EEG.[1] MAC reduction of enflurane in dogs suggests that fentanyl is 10 times more potent than alfentanil.[2] Simulations of effect site concentrations were computed in a three-compartment model using STANPUMP (version 13 June 1995, available from URL:http://pkpd.icon.palo-alto.med.va.gov).

The predicted effect site concentration over 5 h of a fentanyl bolus of 10 µg $kg^{-1}$ given to a 70 kg, 190 cm male was calculated and converted to the equivalent alfentanil effect site concentration using a potency ratio of 10:1. The difference between the equivalent alfentanil effect site concentration and an arbitrary target effect site concentration of 150 ng $ml^{-1}$ may be called the "effect site deficit". Three alfentanil infusion schemes were simulated to fill this theoretical effect site deficit: .25 µg $kg^{-1}$ $h^{-1}$ for 3 h; :50 µg $kg^{-1}$ $h^{-1}$ for 45 min then 25 µg $kg^{-1}$ $h^{-1}$ for 2 h 15 min and a target controlled infusion (TCI) for 3 h (fig. 11).

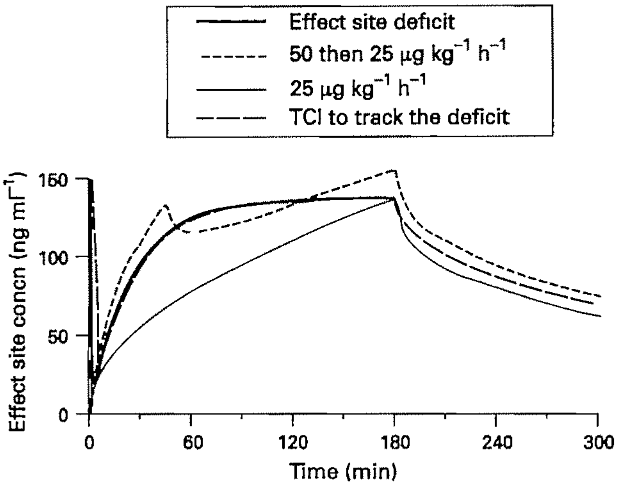

*Figure 11* Effect site deficit and three different alfentanil infusion schemes to fill it.

The quantities of alfentanil used by these infusion schemes were: 25 µg $kg^{-1}$ $h^{-1}$, 5.3 mg; :50 then 25 µg $kg^{-1}$ $h^{-1}$, 6.6 mg and TCI to fill the deficit 6.3 mg. If no fentanyl had been given, 7.3 mg of alfentanil would have been needed to achieve a steady-effect site concentration of 150 ng $ml^{-1}$.

For fentanyl and alfentanil with a potency ratio of 10:1 there was minimal saving in drug usage, and a simple two-step infusion approximated the target-controlled infusion. Perhaps rapid effect site kinetics and expense will make remifentanil more suitable for an effect site target controlled or manual infusion to top-up a long-acting opioid given by bolus or infusion. Potential benefits include intense and cost effective intraoperative narcosis with rapid offset and residual analgesia during recovery.

## More about predicting arterial $P\text{CO}_2$ from end-tidal

P. FOSTER* AND R. FLETCHER
*Department of Anaesthesia, Central Manchester Hospital NHS Trust*

When ventilator rate is halved from 20 to 10 $min^{-1}$, and tidal volume thereby doubled, the resultant change in end-tidal $P\text{CO}_2$ at 20 $min^{-1}$.[1 2] For this study we wanted to see if the estimate of arterial $P\text{CO}_2$ at the lower rate of 10 $min^{-1}$ could be improved, by changing ventilatory rate to 20 $min^{-1}$, simultaneously halving tidal volume.

We studied 24 patients, 20 of them male, undergoing routine cardiac surgery; their mean age was 60 (range 38–73) yr. They were ventilated with enflurane in air/oxygen via a Servo ventilator 900C at 10 $min^{-1}$. Inspiratory and pause time were 25% and 10% of cycle throughout. End-tidal $P\text{CO}_2$ was measured with a Siemens 930 capnograph, calibrated against the blood-gas analyser.[3] At steady state, end-tidal $P\text{CO}_2$ was noted, and then during an expiration the rate was changed to 20 $min^{-1}$, simultaneously halving tidal volume. End-tidal $P\text{CO}_2$ was noted for the first five breaths at the new rate.

The resultant change in end-tidal $P\text{CO}_2$ ranged from −0.4 to 0.1 kPa (in the previous study it ranged from −0.3 to 0.4). However, there was no relationship between the change in end-tidal $P\text{CO}_2$ and the arterial to end-tidal $P\text{CO}_2$ difference at 10 $min^{-1}$ ($r=-0.07$); in the previous study, those patients with the greatest arterial to end-tidal $P\text{CO}_2$ difference showed the greatest increase in end-tidal $P\text{CO}_2$ ($r=0.61$). This method therefore seems unpromising as a basis for refining the end-tidal-based estimate of $Pa_{\text{CO}_2}$ at low ventilatory rates.

The reason for this lack of relationship, and the failure to discriminate between patients with good and bad function, was unclear. Sudden changes in ventilator setting appear to have an asymmetrical effect on $\dot{V}/\dot{Q}$ relationships, depending on whether tidal volume is increased or decreased. It is possible that different functional residual capacities or compliances at the two settings may play a role.

## Antibody microprobe studies of immunoreactive galanin release in the spinal cord of the neuropathic rat

L. A. COLVIN, M. A. MARK AND A. W DUGGAN
*Department of Anaesthetics, Royal Infirmary of Edinburgh, Edinburgh and Department of Preclinical Veterinary Sciences, University of Edinburgh*

After peripheral nerve injury dramatic changes are seen in neuropeptide synthesis in the dorsal root ganglia,[1] with significant increases in galanin and neuropeptide Y mRNA and a decrease in both calcitonin gene-related peptide and substance P mRNA.[2] The aim of this study was to investigate changes in central galanin release after peripheral nerve injury. Although the significance of galanin up-regulation is unknown, it has been postulated to play an inhibitory role in dorsal horn transmission.

Under sodium pentobarbitone anaesthesia, four 4/0 chromic gut ligatures were placed loosely around the right sciatic nerve of male Wistar rats to produce a chronic constriction injury.[3] The International Association for the Study of Pain guidelines for the care of experimental animals were followed.

At 10–14 days after ligature placement, the lumbar spinal cords of urethane-anaesthetized rats ($n=30$) were exposed. Using a micromanipulator, microprobes bearing immobilized antibodies to galanin were inserted into the dorsal spinal cord to a depth of 2.25 mm. After removal from the spinal cord and incubation in $^{125}$I-labelled galanin, autoradiographs of each microprobe tip were analysed using an image analysis system. *In vitro* microprobe images for each experiment were also analysed and normal rats were used as controls. binding of endogenous galanin results in deficits in binding of $^{125}$I-labelled galanin. Mean image analysis of defined groups of microprobes were compared, at 30-µs intervals, and the differences between specified groups were assigned statistical significance using Student's *t*-test.

In normal animals, there was a fairly extensive presence of immunoreactive-galanin throughout the dorsal horn, with a peak in the superficial dorsal horn. In the neuropathic rats there was a significantly greater peak of immunoreactive-galanin release in the superficial dorsal horn ($P<0.05$). As there is significant up-regulation of galanin synthesis in small to medium sized dorsal root ganglia cells, the likely source of this new zone of central galanin release is from primary afferent fibres, affected by the peripheral nerve injury. Since this increased release occurred spontaneously, and there is evidence for spontaneous pain in this model, the two may be linked.

## Oscillations in arterial saturation: implications for the measurement of cerebral blood flow with near infrared spectroscopy

A. T. Lovell*, H. Owen-Reece*, C. E. Elwell*, M. Smith and J. C. Goldstone*
*Departments of Academic Anaesthesia and Medical Physics, University College London Medical School, The Middlesex Hospital, London*

Near infrared spectroscopy (NIRS) is a non-invasive technique to determine cerebral blood flow using oxyhaemoglobin as a tracer.[1] It requires an arterial saturation swing which begins with a stable baseline desaturation. As mild arterial hypoxaemia is induced, oscillations in both arterial saturation and NIRS signals occur. These oscillations occur at the respiratory frequency suggesting a respiratory origin.[2] When arterial saturation oscillates, determining the point at which tracer input occurs becomes difficult, leading to errors in the measurement of flow.

We have developed a two-compartment computer model to examine the effects of changes in cardiorespiratory variables on arterial saturation during a simulated measurement of cerebral blood flow. One compartment represents dead space in which only gas mixing occurs, the other represents alveoli in which both mixing and gas exchange occurs.

During the desaturation phase alveolar oxygen concentration starts at normal values. During quiet respiration it exhibits small oscillations and this produces small changes in arterial saturation owing to the flat nature of the oxygen dissociation curve at this point. However, as the alveolar oxygen concentration declines, the working point on the oxygen dissociation curve moves on to progressively steeper parts of the curve. The consequence of this increasing gradient is that the small oscillations in alveolar oxygen concentration produce progressively larger oscillations in arterial saturation as the mean alveolar oxygen concentration declines.

The model confirms that oscillations in arterial saturation universally occur at respiratory frequency. As the arterial saturation decreases the magnitude of these oscillations increases, the magnitude of the oscillations in alveolar oxygen concentration are relatively constant. The interaction between minute, alveolar and tidal volumes on the magnitude of the oscillation is shown in figure 12.

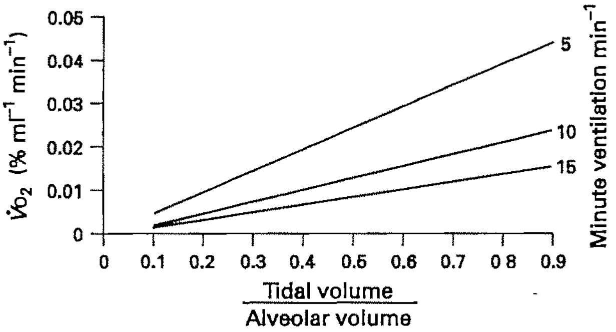

*Figure 12* Interactions between alveolar, minute and tidal volumes on the magnitude of arterial oscillation at a mean saturation of 90%

The model predicts circumstances where the oxyhaemoglobin technique will be impractical and allows optimization of respiratory parameters to enhance measurement of cerebral blood flow.

## Performance of vaporizers in circle systems

D. Wright*, S. Brosnan*, B. Royston and D. White
*Academic Department of Anaesthetics, Northwick Park Hospital, Harrow*

It is generally considered that vaporizers in circuit (VIC) are unsuitable for use with controlled ventilation (IPPV) and this is supported by a number of disasters that have followed the use of this technique. In a completely closed system with VIC, the inspired concentration of agent may rise to dangerous levels, owing to continual recirculation through the vaporizer We have conducted bench tests that confirm this is the case. However, computer simulation (using NARKUP) shows if the fresh gas flow (FGF) is increased above basal, and gas is lost from the system, the increase in concentration of agent is reduced and stabilizes at a level dependent upon the FGF.

This work suggested that VIC can be safely used with IPPV (provided agent monitoring is used) without adverse effects. We studied 20 patients, ASA I-II, having routine major orthopaedic surgery. Anaesthesia was induced with propofol and neuromuscular blockade achieved with vecuronium before intubation. In theatre, patients were attached to a Scania circle system with a Komesaroff vaporizer mounted in the inspiratory limb and ventilated using a Nuffield Penlon ventilator. Inspired and expired isoflurane and carbon dioxide concentrations were measured using a calibrated Datex Ultima analyser. Minute ventilation was adjusted to maintain an end tidal carbon dioxide of 4.0–4 5 kPa. The vaporizer settings were initially between 1 and 1.5 which gave an adequate inspired concentration of isoflurane in the circuit. Patients received either 1, 2 or 3 litre FGF.

In no case was the inspired anaesthetic concentration uncontrollable. After the first 10 min in theatre, the inspired concentration of isoflurane was stable (fig. 13).

At the lowest FGF used, the concentration of isoflurane tended to increase initially and in the majority of the patients required reduction of the vaporizer setting, after which no further adjustments were necessary. This effect was seen to a lesser degree at the 2- and 3-litre flow rates. We have shown that vaporizers can be

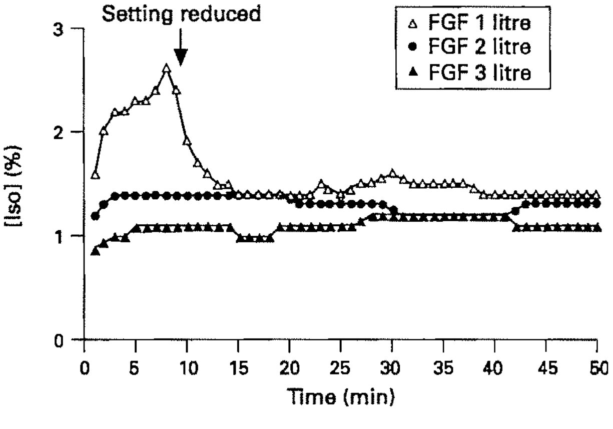

*Figure 13* Inspired isoflurane concentrations for three patients anaesthetized using VIC with three fresh gas flow rates (FGF).

used reliably and safely in the circle system. The stability of the anaesthetic concentration is conferred by controlled leakage from the system.

## Sequential veno-venous haemofiltration in the treatment of multisystem organ failure

Z. Molnar*, E. Shearer and D. Lowe*
*University Department of Anaesthesia, Liverpool and Intensive Care Unit, Fazakerley Hospital, Liverpool*

It has been suggested that haemofiltration has the potential benefit of removing inflammatory mediators and hence improving survival in multisystem organ failure.[1] The aim of this retrospective study was to evaluate the effects of sequential veno-venous haemofiltration (SVVH) on morbidity and mortality, when used as an early, elective treatment in critical illness to prevent the onset or progress of multisystem organ failure.

Fifteen critically ill patients with normal renal function (8 male, 7 female; age: median (m)=45, range (r)=16–65 yr) had undergone elective SVVH during an 18-month period. We compared survivors and non-survivors by their age, admission Apache II scores, predicted mortality, multiple organ dysfunction scores (MODS)[2] and haemofiltration characteristics. All patients received routine intensive care management, and the haemofiltration was started within 48 h of admission to the intensive care unit. For statistical analysis, Mann-Whitney and Fisher's exact tests were used.

Eight patients survived and seven died. There was no significant difference in age between the two groups (survivors: m=49, r=16–65; non-survivors: m=45, r=30–65). Apache II scores were higher in survivors (m=18, r=10–21) than non-survivors (m=14, r=7–20) as was predicted mortality (m=22, r=13–35% in survivors and m=11, r=7–20% in non-survivors). MODS before the onset of SVVH treatment was higher in non-survivors (m=7, r=4–12) than in survivors (m=5, r=0–8). None of these differences achieved statistical significance. All patients received daily SVVH up to a maximum of six treatments. There was no difference in the average total volume exchange during SVVH between survivors and non-survivors. The total fluid deficit during the course of the SVVH treatments was significantly higher in non-survivors (extracted fluid in litres: survivors: m=2.5, r=0–8; non-survivors: m=7, r=5–10; $P$=0.01). None of the survivors developed renal impairment, but five non-survivors subsequently developed acute renal failure. Heparin and epoprostenol sodium were used for anticoagulation during the treatments and we could not find any difference between their effects on physiological factors.

**Key words**
Blood, haemofiltration. Complications, multisystem organ failure.

## Comparison of two wrapping systems for heat retention during anaesthesia

S. Deacock and A. Holdcroft
*Department of Anaesthesia, Royal Postgraduate Medical School, London*

Hypothermia can complicate anaesthesia. The use of active and passive warming methods should transmit an adequate amount of heat to maintain body temperature. The choice of passive methods includes body wraps some of which may prevent evaporative and convective heat loss, such as plastic bag, and others with reflective properties which could protect against radiation heat loss. It was hypothesized that, during prolonged major abdominal surgery, a plastic bag would be as effective in preventing heat loss as the more complex wraps incorporating reflective surfaces.

Forty patients presenting for hepatobiliary surgery were studied after informed consent. Two systems were used at random for heat retention: group 1 wore the Thermadrape garment (Vital Signs Ltd, Brighton), and group 2, large, transparent, thin plastic bags on the limbs and head. Active conduction of heat was standardized using a warm air mattress and blood warmers. An ambient theatre temperature of more than 21 °C was maintained. A nasopharyngeal probe measured core temperature and four peripheral skin temperature probes were used to calculate the mean skin temperature.[1] Measurements were taken every 15 min during surgery and the body heat calculated using the patient's weight. A standardized anaesthetic technique was used: induction with thiopentone and fentanyl, and vecuronium for neuromuscular block. After tracheal intubation, anaesthesia was maintained with oxygen, nitrous oxide and isoflurane in appropriate concentrations using intermittent ventilation of the lungs, through a heat and moisture exchanger. Additional analgesia was provided either with i.v. fentanyl or a thoracic extradural infusion of fentanyl and bupivacaine.

The two groups were similar with respect to age, weight, duration of operation, surgery performed, blood loss and anaesthetic technique. The mean core temperature increased by 1.5 °C (from 35.8 to 37.3 °C) in group 1 and by 1.4 °C (from 35.8 to 37.2 °C) in group 2. When core temperature increased above 37.5 °C active heating was stopped and cooling commenced. This occurred in two patients in each group. A mixed model analysis of variance was used to compare the relationship between heat intake and the time course of anaesthesia between the two groups. Both groups gained heat at about 50 kJ $h^{-1}$ for the first 3 h of surgery but after this heat gain continued in group 2 but not group 1.

Both systems of wraps for heat retention during surgery were effective in preventing heat loss and when combined with other methods produced hyperthermia. At the higher body temperatures achieved after 3 h of surgery, a change in the heat dissipation mechanisms may have produced the differences in heat gain observed between the two wrapping systems.

## Effect of a bolus dose of midazolam on the auditory evoked response in humans

J. Umo-Etuk*, R. M. Sharpe*, M. D. Brunner* and C. Thornton
*Academic Department of Anaesthesia, Imperial College of Medicine at St Mary's, Northwick Park Hospital, Harrow*

Although midazolam given as a bolus has been shown to suppress the amplitudes and extend the latencies of the late cortical (N1, P1, N2, P2) and cognitive (P300) auditory evoked responses (AER) it has little effect on the early cortical AER waves Pa and Nb.[1] This has to be reconciled with the claims that features of the early cortical AERs indicate loss of awareness[2] and midazolam produces hypnosis. As the patient falls asleep Nb latency lengthens. The 50% cut-off from a discrimant function analysis was 44.5 ms.

Nine patients, aged 24–49 yr, were studied. None was premedicated and midazolam was given as a bolus of 20 mg over 5 s. The times until the eyelash reflex was lost and the airway required support were recorded. The AER was elicited by 75 dB (above HL) clicks presented binaurally at a rate of 6 ps. The EEG from which the AER was derived was recorded from silver-silver chloride cup electrodes attached to the scalp using collodion glue at the vertex and inion. These electrode sites were used in preference to the usual forehead and mastoid site to ensure better recordings in the awake patient. Nb latency was measured when the patient was awake, after loss of eyelash reflex and after requirement for airway support. The AER waveforms were averaged over 1024 sweeps, where possible, but occasionally, because the time to lose these reflexes is uncontrolled a shorter number of sweeps were used.

The eyelash reflex was lost 1.78 (0.50) min (mean (SD)) after the midazolam bolus. Two of the patients did not require airway support in the 10 min allowed for the study. The time to airway support for the rest of the patients was 2.74 (1.26) min. The effect of midazolam on Nb latency recorded immediately after these events is shown in figure 14. Analysis of variance was used and when the Bonferroni adjustment, for multiple comparisons, was applied there were significant differences between Nb latency from awake to loss of eyelash ($P<0.001$) and awake to airway support required ($P=0.003$).

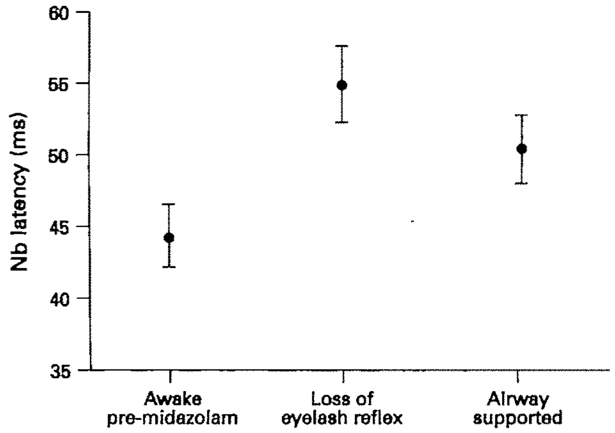

*Figure 14* Nb latency (means+95% CI) after a midazolam bolus.

We concluded that loss of consciousness induced by a midazolam bolus and indicated by loss of eyelash reflex and requirement for airway support was associated with a significant increase in Nb latency. This supports previous work[2] where a significantly increased Nb latency was related to loss of consciousness judged by loss of response to verbal command. However, we noted that even with the substantial dose of midazolam, which we gave, there was a variable effect in the time taken to these clinical end-points, if in fact they occurred at all. It is conceivable that smaller doses, combined with the variable response of the patient, may not necessarily achieve loss of consciousness. This would account for reports of intraoperative awareness, in particular the perception of auditory stimuli during anaesthetic regimes where benzodiazepines are used to suppress consciousness.[1]

## Changes in the early cortical auditory evoked response during hypothermia

C. C. POPLAR AND D. C. SMITH
*Department of Anaesthesia, Southampton General Hospital, Southampton*

We have previously reported[1] the general effects of reduced core temperature on the auditory evoked response (AER). This study examines the association in more detail.

We recorded the AER in 42 adults during cardiopulmonary bypass (CPB) for elective coronary artery grafting. Premedication was diazepam 10–15 mg, morphine 10–15 mg and prochlorperazine 12.5 mg. Rarefaction clicks at 6.12 Hz and 65 dB loudness were played through moulded earpieces into both ears. The EEG was recorded between disposable silver-silver chloride electrodes (Medicotest P-00-S) on the mastoid processes and the vertex, using one mastoid electrode as ground. The resulting signal was digitized at 1 kHz and stored on computer disk. The AER was derived using the Northwick Park software, averaging 512 sweeps of 125-ms epochs of the EEG. Anaesthesia was induced with fentanyl 10 $\mu g\ kg^{-1}$, thiopentone 1 mg $kg^{-1}$ and pancuronium 12 mg. Anaesthesia was maintained with a further dose of fentanyl 5 $\mu g\ kg^{-1}$ before sternotomy and 0–1% isoflurane in the anaesthetic room then a propofol infusion 1–3 mg $kg^{-1}\ h^{-1}$. We recorded a baseline AER during stable conditions after, dissection of the internal mammary artery and then during cooling to 26 °C and subsequent rewarming to 37 °C on cardiopulmonary bypass at a mean arterial pressure of 40–70 mm Hg. The latency and amplitude of the Pa and Nb waves of the early cortical AER were measured for each 0.5 °C change in nasopharyngeal temperature (used as an approximation of brain temperature). Statistical analysis was done with one-way repeated measures ANOVA and *t*-testing, using SPSS for Windows and accepting significance at the 5% level.

The latencies of both the Nb and Pa waves increased with decreasing temperature between 37 °C and 28 °C ($r=-0.70$), the change from the baseline at 37 °C becoming statistically significant at 34.5 °C for both waves. The amplitude of the Pa wave was difficult to measure reliably. The amplitude of the Nb wave decreased with temperature, but the correlation was weak ($r=0.25$) as a result of wide variability in Nb amplitude at each temperature (table 7).

*Table 7* Mean latency (ms (SD)) of the early cortical waves of the AER

| | Temperature | | | | | |
|---|---|---|---|---|---|---|
| | 32 °C | 33 °C | 34 °C | 35 °C | 36 °C | 37 °C |
| Pa wave | 53.2 (11) | 46.4 (9) | 40.5 (9) | 38.2 (7) | 37.3 (6) | 34.5 (5) |
| Nb wave | 74.5 (11) | 67.3 (10) | 60.9 (9) | 58.6 (8) | 58.2 (8) | 55.5 (5) |

The effect of temperature on the AER is not significant until the patient is quite cold, so can probably be ignored during anaesthesia for most non-cardiac procedures.

**Key words**
Monitoring, evoked potentials. Temperature, effect. Measurement techniques, electrophysiology.

## Effect of sevoflurane on the auditory evoked response, spectral edge and median frequency in humans

R. M. SHARPE*, S. BROSNAN*, C. THORNTON, C. J. DORÉ* AND D. E. F. NEWTON
*Academic Department of Anaesthesia, Imperial College of Medicine at St Mary's, Northwick Park Hospital, Harrow*

The low blood-gas solubility of sevoflurane allows rapid changes in anaesthetic depth. In paralysed patients a reliable monitor of anaesthetic depth would be useful with this agent. This study compared the effect of sevoflurane on the auditory evoked response (AER) with the derived electroencephalogram (EEG) variables, that is median frequency (F50) and spectral edge (F95).

Twelve patients (aged 31–65 yr) gave informed consent to participate in a crossover study which had been approved by the Harrow Research Ethics Committee. After premedication with morphine 10 mg and atropine 0.4 mg, anaesthesia was induced by inhalation of sevoflurane in 66% nitrous oxide in oxygen. The patients were intubated after vecuronium 0.1 mg $kg^{-1}$ Subsequently, neuromuscular paralysis was maintained at a level of two twitches (TOF count) by vecuronium infusion. The EEG and AER were recorded throughout four consecutive 10-min periods. During each period, patients were maintained at end-tidal sevoflurane concentrations (0.5, 1 and 2%) in random order. In the fourth period, the concentration of the preceding period was repeated. This ensured that each concentration was preceded by every other concentration including itself an equal number of times. This design ensured that any "carryover" effect between periods would cancel out and allowed interaction between dose and time to be studied.

End-expiratory concentrations of sevoflurane, nitrous oxide and carbon dioxide were measured using a calibrated Datex Ultima gas analyser. Ventilation and fresh gas flow were adjusted to maintain an end-expiratory carbon dioxide between 4.5–5 kPa. For each concentration of sevoflurane, the AER and EEG analysis was carried out in the final 2.5 min of the 10-min period (when equilibrium was considered to have occurred). Analysis of variance was carried out on the $\log_{10}$ transformed data. A significant linear effect of dose was seen for all variables (see table 8).

*Table 8* Effect of sevoflurane concentration on AER and EEG variables (geometric means (95% confidence intervals))

| Variable | *P* value | 0.5% Sevo | 1% Sevo | 2% Sevo |
|---|---|---|---|---|
| Pa 1st | 0.01 | 35.5<br>(32.7–38.9) | 40.7<br>(37.2–44.7) | 42.4<br>(38.7–46.4) |
| Pa amp | <0.001 | 0.34<br>(0.25–0.46) | 0.19<br>(0.14–0.27) | 0.11<br>(0.08–0.15) |
| Nb 1st | 0.04 | 54.7<br>(50.1–59.7) | 59.6<br>(54.6–65.0) | 63.7<br>(58.3–69.5) |
| Nb amp | <0.001 | 0.26<br>(0.20–0.33) | 0.18<br>(0.14–0.23) | 0.11<br>(0.08–0.14) |
| F50 | <0.001 | 3.1<br>(2.6–3.7) | 2.1<br>(1.8–2.6) | 1.5<br>(1.3–1.8) |
| F95 | <0.001 | 15.8<br>(14.7–17.1) | 13.1<br>(12.1–14.1) | 7.9<br>(7.3–8.6) |

The results demonstrated that the AER and EEG derived variables had a linear relationship with the dose of sevoflurane, as previously demonstrated with desflurane.[1] Regression equations for each variable were calculated to give a percentage change for a 1MAC change in sevoflurane concentration. For example a 1MAC increase in sevoflurane concentration produces a 51% (95% confidence intervals 36–62) decrease in Pa amplitude and a 35% (29–40) decrease in F95. These percentage changes were similar to 1MAC percentage changes for desflurane where Pa amplitude decreased by 49% (40–56) and F95 decreased by 33% (25–41).

This confirms that analysis of AER and EEG variables continues to be a useful research tool in the search for a monitor for depth of anaesthesia.

## Use of a photographic method to compare rigid laryngoscopy techniques

P. Groom, M. Hawkins, R. Hancock and P. Charters
*Department of Anaesthesia, Aintree Hospitals, Liverpool and Department of Medical Photography, Aintree Hospitals, Liverpool*

The basis for a method to compare the relative efficiency of laryngoscope blades has been outlined.[1] This requires use of a standardized intubating position,[2] mouth closed around the blade, consistent technique, controlled displacement of the larynx, accurate photographic record of view of laynx,[3] and that the blade should be positioned below the epiglottis. (The latter allows reasonable comparisons between straight and curved blades.) This pilot study compares a Macintosh 3 blade with the narrow Sheila Anderson straight blade of equivalent length, in subjects who were not expected to be difficult laryngoscopies.

Ten subjects (ASA I–II) scheduled for tonsillectomy or nasal surgery were recruited. Patients at risk of oesophageal reflux or with a history of difficult intubation were excluded. Oral premedication was with diazepam 10 mg. After preoxygenation, anaesthesia was induced with midazolam (0.04 mg $kg^{-1}$), propofol (2 mg $kg^{-1}$) and vecuronium (0.15 mg $kg^{-1}$) and maintained with a standard propofol infusion plus hand ventilation with equal volumes of oxygen and nitrous oxide. When the train-of-four suppression was complete, alfentanil (15 $\mu g$ $kg^{-1}$) was given just before laryngoscopy. Photographic records were made of the view with each laryngoscope. The photographer used a fixed focal distance and moved to a position along the optimum eyeline till the cords were in sharp focus. (In each case view with the Macintosh blade was assessed before the straight blade.) When each view was recorded a simultaneous lateral photograph of the head and neck position was taken to check the position. All the patients were followed up at 4–6 h postoperatively.

A good record was considered to be one where the upper teeth or lip and posterior part of the laryngeal inlet or arytenoids were adjacent on the photographic image. In all the cases except one, good views of the larynx were obtained. In this case view with the Macintosh blade was satisfactory but poor control of the epiglottis did not allow a good view with the straight blade. Otherwise the view with each blade was comparable.

The maximum depth of laryngeal exposure measured in these subjects was 1.5 cm. In no case was all of the larynx visible on the image even though this was usually the case as far as the anaesthetist was concerned. As has been documented in earlier work, the photographic image is not the same as the composite perceived by the anaesthetist who scans the larynx by panning to determine how much of the larynx can be visualized.[3] This is a limitation of this method, but this "restricted window" effect may well be relevant only when the view is good and unimportant when little or no part of the larynx is visualized.

## Development of a computer system for prediction of difficult laryngoscopy

D. F. Gillies*, M. A. F. Rodrigues*, P. Charters and R. R Marks
*Department of Computing, Imperial College, London, Department of Anaesthetics, Walton Hospital, Liverpool and Department of Anaesthetics, Royal London Hospital, London*

Failed intubation remains an important life-threatening event under anaesthesia. Currently, anaesthetists attempt to anticipate the degree of difficulty from the medical and anaesthetic history and relevant clinical examination by way of simple bedside tests.[1] The incidence of difficulty in intubation is said to be between 1.2% and 2.5%. Of these, 75% of the cases have been claimed to be predictable, though this figure also includes 12% of false positive predictions.[2] However, it is in the remaining 25%, that cannot be predicted preoperatively by the above conventional medical procedures, that present the anaesthetist with the greatest difficulty.

We developed a computer simulation to predict difficult intubation cases from historical patient data. The system was based on mathematical models of the laryngoscopy process.[3] Users of the system were able to select, position and orientate different blade types on a computer screen which showed a stylized cross-section of the airways. Blade movements which were responsible for tongue deformation were guided by pressing the mouse buttons. These movements were restricted, first, by the incisors and, second, by the tongue compressed between the blade and the inner boundaries of the lower jaw. Geometric constraints were made explicit either as imposed conditions that cannot be violated (for example, the point representing the tip of the incisors cannot penetrate the blade) or as monitored conditions whose violation was reported to the user (for example, when the tongue became maximally compressed). Measures relating to difficult intubation were calculated, and a simulated view of part of the vocal cords was drawn. This provided an intuitively simple way of grading the difficulty of laryngoscopy relative to the cord visualization. Simulation results such as charts and images were saved to files for later demonstration, analysis and clinical diagnosis.

Preliminary evaluation of the system has been carried out using patient histories and the subjective assessments of experienced anaesthetists, and the results are encouraging. A more comprehensive prospective systematic study, involving 20 patients is currently being undertaken .

## Inhibition of nitric oxide synthase antagonizes curare-induced tetanic fade

J. R. Hood, G. Lees and C. Durrant*

*Department of Anaesthetics, Imperial College School of Medicine at St Mary's Hospital, London*

Nitric oxide modulators have been shown to influence the contractility of directly stimulated muscle[1] and to affect spontaneous synaptic currents in the embryonic neuromuscular synapse.[2] To study the macroscopic effect of this class of drug we have investigated the actions of the nitric oxide synthase inhibitor, 7-nitroindazole, upon curare-induced fade in the rat hemidiaphragm.

Left hemidiaphragms of male Sprague-Dawley rats (280–320 g) were isolated and mounted in a bath of Krebs-Henseleit solution containing 0.5 µmol litre$^{-1}$ tubocurare at 32 °C perfused with 95% oxygen/5% carbon dioxide. Single 0.2-ms pulses of supramaximal voltage (5–8 V) were applied to the phrenic nerve and the resultant twitch responses transduced and recorded. Upon stabilization, tetani of 2-s duration were administered. One tetanus was applied, at 1-min intervals, at each of the following frequencies: 10, 20, 25, 30, 35, 40, 50 and 75 Hz The bathing solution was then replaced with one containing the study drug, and after a 30-min incubation period, the same pattern of tetani was repeated.

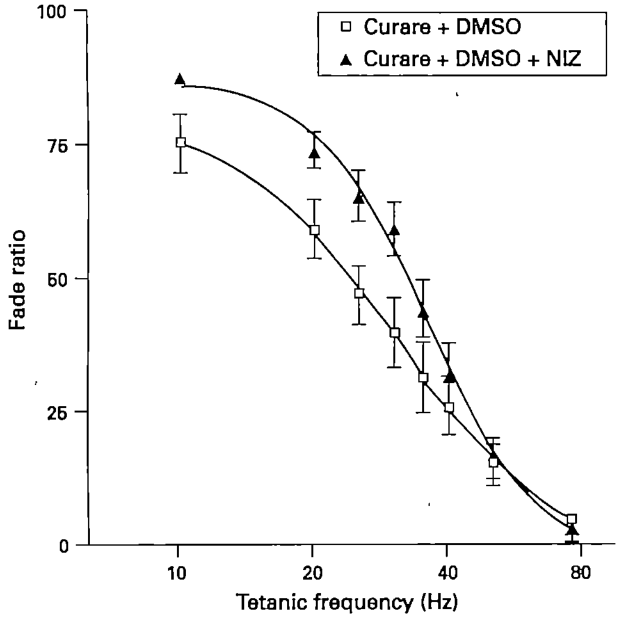

*Figure 15* Results. $n$=6 for both groups. The two groups are significantly different ($P$<0.01, ANOVA).

A curare solution 0.5 µmol litre$^{-1}$ with 7-nitroindazole 0.32 mmol litre$^{-1}$ plus 0.104% dimethyl sulphoxide solvent was compared with one without the 7-nitroindazole. The fade ratios at each frequency of their tetanic trains were measured and fitted to frequency response curves by non-linear regression using GraphPad Prism software. The two sets of results were compared by two-way ANOVA.

Mean (SEM) results for dimethyl sulphoxide with and without 7-nitroindazole are shown in figure 15.

The finding that 7-nitroindazole antagonizes curare-induced tetanic fade supports the belief that nitric oxide decreases quantal release in the neuromuscular junction.[2]

## Persistent pain of reflex sympathetic dystrophy

R. Stevens, J. Barclay, M. Powar, C. Shin and T-C. Kao

*Pain Management Center, Loyola University, Maywood, Illinois, USA*

The pain of reflex sympathetic dystrophy (RSD) or complex regional pain syndrome in the upper extremity has been traditionally treated with repeated stellate ganglion blocks (SGB) in expectation of providing increasing duration of pain relief to arrest the pain syndrome. There are few data regarding efficacy of SGB or supporting the notion that subsequent SGB will provide in increasing duration of pain relief.

We studied 25 consecutive patients with upper extremity RSD of greater than 12 months' duration who met five of nine criteria for the diagnosis of RSD: (1) diffuse burning pain of the hand, (2) relief of pain after SGB, (3) colour difference between hands, (4) allodynia/hyperpathia, (5) temperature difference between hands >1 °C, (6) oedema, (7) sudomotor symptoms, (8) decreased range of motion of hand or wrist, (9) trophic changes of the skin. Data were collected using a standardized history and physical examination. Data were reported as mean (SD) (range), or percentage.

Patient characteristics were: sex 36% M; 64% F; duration of pain: 52 (45) months (range 12–184); visual analogue pain score (0–10): 6.9 (2.5) (range 2–10). Mean number of SGB per patient was 17.7 (39) (range 9–200). Of the 24 patients who reported relief of pain after SGB, median pain relief was 40 h. Only one patient who had relief of pain after SGB reported an increasing duration of analgesia with subsequent SGB. Opioids were used by 88% of patients, with mean daily oral morphine equivalent dose of 37 (59) mg (range 5–240). Tricyclic antidepressants were used by 72%, and other antidepressants by 16%. Anticonvulsants were used by 12%. Twenty-four percent of the patients were currently undergoing hand therapy, although it had originally be prescribed for all

Our results and those of Veldman,[1] who used similar diagnostic criteria, revealed a subset of RSD patients whose pain was not cured despite aggressive and early SGB. These patients did not demonstrate an increasing duration of analgesia with subsequent blocks. Continuation of SGB appeared to be without justification. Hand therapy appeared to be too painful for most of these patients, so they refused to continue. For the majority of RSD patients refractory to SGB therapy, oral medications were helpful in providing analgesia.

## Nitrous oxide enhances the spread of spinal analgesia

A. Fassoulaki, C. Sarantopoulos* and M. Zotou*
*Department of Anaesthesia, St Savas Hospital, Athens, Greece*

Systemic opioids enhance the spread of spinal analgesia produced by lignocaine.[1 2] Nevertheless, systemic opioids may be associated with undesirable effects. In the present study we investigate the effect of 50% nitrous oxide on the spread of spinal analgesia.

Forty patients undergoing transurethral prostatectomy under spinal anaesthesia were studied. In the operating room all patients received Ringer's lactate solution 500 ml and an $F_{IO_2}$ 0.35 via a Ventimask. Spinal anaesthesia was performed with the patient in the left lateral position. After local infiltration with 2% lignocaine, 5% hyperbaric lignocaine 100 mg (Xylocaine, Astra SG 1030-1035) was injected in the L3-4 interspace via a 25 gauge Whitacre needle, and the patient was placed in the lithotomy position. The level of spinal analgesia was established 20 min after spinal injection by means of a pressure feeler. Then patients received randomly either 50% nitrous oxide in oxygen (nitrous oxide group) or 50% nitrogen in oxygen (control group). The level of spinal analgesia was reassessed 10 min later under nitrous oxide or nitrogen inhalation. The nitrous oxide or nitrogen were discontinued, and the level of analgesia was reassessed 5 min after discontinuation. All assessments were done behind a screen by the same anaesthetist who was unaware whether nitrous oxide or nitrogen was administered. Results were analysed with unpaired Student's *t*-test.

Patient characteristics were similar in the two groups. One patient in the control group was excluded owing to a high level of spinal anaesthesia. Results are given in table 9.

*Table 9* Changes to the pressure feeler response in cm (mean (SD)) for each group (*$P<0.001$, **$P<0.01$, †$P=0.024$). In cols 1 and 3 time is compared with basal (20 min after block) and in col 2 time is compared with col 1

| Group | 10 min after $N_2O$ or $N_2$ inhalation | 5 min after $N_2O$ or $N_2$ discontin. | 35 min after spinal anaesthesia |
|---|---|---|---|
| $N_2O$ (n=20) | 1.56 (1.97)* | −3.52 (2.29)** | −2.20 (2.89)† |
| Control (n=19) | −3.14 (2.67)* | −1.46 (1.37)** | −4.53 (3.28)† |

These data suggested that inhalation of 50% nitrous oxide enhanced the spread of spinal analgesia. This effect subsided rapidly 5 min after nitrous oxide discontinuation, but still a significant difference was found compared with the control group.

**Key words**
Anaesthetic techniques, spinal. Anaesthetics gases, nitrous oxide.

## Mid-tarsal block for surgery on the forefoot; what is the optimal local anaesthetic mixture?

G. J. Haldane and M. G. Serpell
*Department of Anaesthesia, Western Infirmary, Glasgow*

The mid-tarsal block allows the performance of surgery on the foot while the patient is awake and also provides analgesia for the postoperative period.[1] This block is performed distally where the nerve fibres are smaller and therefore are blocked quickly by local anaesthetics so delay of onset is not usually a clinical problem. When the block recedes, however, the patient can experience severe pain and half require parenteral opioids.[2] If a local anaesthetic mixture could provide prolonged analgesia this would improve the patient's comfort and ability to perform physiotherapy. This was investigated by a prospective, randomized double-blind trial.

Sixty-two patients scheduled for elective surgery of the forefoot were randomized into four groups depending on the local anaesthetic mixture used to provide the nerve block. Groups LBA and LB consisted of a 50:50 mixture of 2% lignocaine and 0.5% bupivacaine with or without adrenaline 1/200 000 respectively. Groups BA and B consisted of 0.5% bupivacaine with or without adrenaline 1/200 000 respectively. Patients received increments of midazolam 1–2 mg i.v. as required for sedation. Non-invasive blood pressure, pulse oximetry and electrocardiogram were monitored. The foot was exsanguinated and an ankle tourniquet inflated to 250 mm Hg. When surgery was completed patients were prescribed analgesia as oral coproxamol two tablets, 4 hourly (maximum 8 in 24 h) or i.m. morphine 0.15 mg $kg^{-1}$ 3-hourly. Time to first analgesia (TFA) or for block to completely wear off was noted. Visual analogue scale (VAS) pain scores were recorded at TFA and at 24 h, and analgesic consumption noted.

Four patients (one from each group) were withdrawn from the study owing to incomplete block (LBA and BA), unable to tolerate tourniquet (B) and a more minor operation being performed than planned (LB). Demographic variables were similar in all groups. Group BA had a significantly longer duration of block or TFA than both groups LB and LBA. VAS pain scores at TFA were similar; however, those at 24 h in the LB group were less than those in the two groups containing adrenaline. The 24-h morphine consumption was higher in both lignocaine groups (table 10).

*Table 10* Perioperative variables. Data displayed as mean (SD) or median interquartile range). Morphine consumption expressed as number (*n*) of doses. *$P<0.02$ for LBA and BA (ANOVA); †$P<0.05$ for LB and LBA; ††$P<0.05$ for LBA; **$P<0.02$ for LBA and BA (Kruskal-Wallis)

| | Group (*n*) | | | |
|---|---|---|---|---|
| | LB (13) | LBA (17) | B (12) | BA (16) |
| Block duration or TFA (h) | 10.7 (3.7) | 11.5 (3.3) | 12.3 (4.7) | 15.5 (4.8)* |
| 24 h | | | | |
| Morphine (*n*) | 0.7 (0.8) | 0.6 (0.6) | 0.2 (0.4)† | 0.3 (0.4)†† |
| Pain VAS | 8 (3–19)** | 29 (8–47) | 18 (9–34) | 31 (19–61) |

All groups provided good operative anaesthesia. The adrenaline-containing mixtures are a safe combination to use provided there is no pre-existing vascular insufficiency and vascular injection is avoided.

The BA combination provided the longest duration of postoperative analgesia and a low opioid consumption in the first 24 h. However, at 24 h this group had higher pain VAS scores. This may be related to either the low morphine consumption or perhaps the action of adrenaline which is involved in peripheral sensitization.

## Comparison of dural indenting between Whitacre and Quincke tipped spinal needles

L. Anderson*, S. Marshall, C. Brydon* and M. G. Serpell
*Department of Anaesthesia, Western Infirmary, Glasgow*

There is some concern over the increased failure rate for spinal anaesthesia with pencil point compared with conventional Quincke tipped spinal needles.[1] The reason for this may be because the lumen of the side hole is not entirely within the subarachnoid (SA) space at the moment when cerebrospinal fluid

(CSF) is first detected. This could result in partial failure to administer the local anaesthetic to the SA space. It has been suggested that this problem can be overcome by advancing the needle a further 1–2 mm from the point when CSF is first detected.[2] However, this would predispose the neural tissues to an increased risk of contact by the needle tip with resultant paraesthesia or damage.[3] We aimed to document and compare the amount of dural indentation which occurred before penetration of a blunt Whitacre (pencil point) and sharp Quincke tipped spinal needle during dural puncture.

We recruited 28 patients scheduled for elective TURP or TURBT under SA anaesthesia. Patients were randomized into two groups depending on whether a Whitacre 25 gauge or Quincke 25 gauge spinal needle was used. I.v. access and standard monitoring was established. Lumbar puncture was performed in the midline at the L2-3 interspace with the patient in the sitting position. After the needle was inserted into the ligamentum flavum, the stylet was removed and the needle connected to a pressure transducer. The needle was slowly advanced until the extradural space had been entered and the length of needle remaining outside the patient was measured (A). The needle was then advanced until a reduction in pressure was recorded; this is believed to be the point when the dura starts to indent. The length of needle is again measured (B). As the needle is slowly advanced, the pressure becomes progressively less until the dura is punctured, when a positive pressure indicates that the SA space has been entered. At this point the length of needle is once more measured (C). The distance between B and C represents the amount of dural indenting before puncture. With the study completed, patients were managed as usual.

Patient characteristics, extradural and subarachnoid distances and pressures were similar for the Whitacre and Quincke groups. In a similar proportion of subjects from each group only points A and C were identified. In the remaining subjects (*n*) in which indenting was seen, the pressure recorded just before dural puncture was significantly lower in the Whitacre group (table 11).

*Table 11* Data expressed as mean (SD) or median (IQ range) (*$P<0.02$ Mann-Whitney)

| | Group (n/N) | |
|---|---|---|
| | Whitacre (10/16) | Quincke (9/12) |
| Distance to dura (mm) | 1.5 (0.5–2.0) | 0.5 (0.5–1.0) |
| Dural indent (mm) | 2.25 (1.6–2.9) | 2.5 (1.5–3.0) |
| Lowest pressure (mm Hg) | −31.5 (−22.5 to −56) | −1.5 (0.5 to −5.5)* |

In a closed system, the dura was no more compliant when a Whitacre tip was used compared with a Quincke. However, a greater negative pressure was generated before the needle could puncture it. This would explain the palpable "click" experienced with these needles. The increased pressure gradient would favour retraction of the dura back to its original position. This evidence would favour the cessation of the practice of needle advancement which, in our view, is unnecessary.

## Enhanced spinal cord Fos expression following thermal injury in the mononeuropathic rat

**M. J. Hudspith and R. Munglani**
*University Department Anaesthesia, Addenbrooke's Hospital, Cambridge*

After nerve injury, altered processing of subsequent noxious stimuli may contribute to the development and maintenance of chronic pain states. The activation of pathways involved in spinal cord pain transduction can be mapped using the protein product of the immediate early gene *c-fos*; Fos protein being expressed rapidly in laminae 1-2 of the spinal cord as a monosynaptic response to C-fibre activation by peripheral noxious stimuli.[1] We therefore examined spinal cord Fos expression in response to thermal injury in a chronic constrictive nerve injury model of neuropathic pain.[2]

Male Sprague Dawley rats (five per group) were anaesthetized with halothane and underwent either loose ligation of the left sciatic nerve or sham operation: control animals underwent no surgery. Animals were allowed to recover for 14 days when animals in the stimulated group were re-anaesthetized and the left hind paw immersed in a water bath at 52 °C for 20 s; non-stimulated group animals were similarly anaesthetized but not exposed to the noxious thermal stimulus. Animals were allowed to recover for 2 h after which they were killed and Fos expression in the L4-5 spinal cord was quantified using an antibody to c-fos protein visualized by a diaminobenzidine peroxidase technique.[1] Data were expressed as means (SEM) and statistical analysis was by ANOVA with Bonferroni-Dunn correction.

Both nerve ligation and sham operation resulted in a persistent bilateral increase in Fos expression in laminae 3-4 and 5-10 when compared with control animals as has been reported previously.[3] However, little or no Fos expression in laminae 1-2 was evident in any non-stimulated animals. Thermal injury produced a large ipsilateral increase in laminae 1-2 Fos expression in all stimulated animals. Thermal injury caused significantly greater ipsilateral laminae 1-2 Fos expression in ligated animals than control animals ($P<0.01$); laminae 1-2 Fos expression in sham-operated animals did not differ significantly from control animals (fig. 16). Thermal injury did not significantly alter Fos expression in deeper laminae of the spinal cord in any animals.

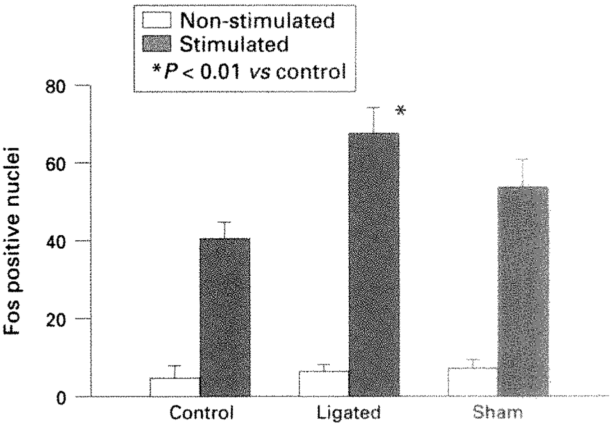

*Figure 16* Ipsilateral laminae 1-2 Fos (nuclei per section (SEM), n=5).

These data indicated that processing of nociceptive C-fibre afferent input was altered after neuropathic injury. Increased monosynaptic activation of dorsal horn neurones may be a result of enhanced C-fibre input and/or sensitization of central synaptic mechanisms.

## Direct effects of suxamethonium on one paramyotonia congenita-mutant (R 1448H) of voltage-gated muscle sodium channels?

**M. Leuwer**, G. Haeseler*, K. Weckbecker*, S. Piepenbrock* and R. Dengler*
*Department of Anaesthesiology and Department of Neurology, Hannover Medical School, Germany*

Recently Vita and colleagues[1] reported two sisters suffering from myotonia fluctuans who presented masseter muscle rigidity and whole-body rigidity during induction of anaesthesia after suxamethonium. Myotonia fluctuans and other closely related disorders, for example, paramyotonia congenita (PC), are caused by several point mutations in the α-subunit of SCN 4A, the gene encoding the adult isoform of voltage-gated muscle sodium channels.[2] Therefore, we investigated possible direct effects of suxamethonium on one mutant sodium channel (R 1448H) causal in PC.

In human embryonic kidney cells expressing either the wild type (WT) or the mutant R 1448H of the human skeletal muscle sodium channel standard voltage-clamp whole-cell experiments were performed at 20 °C.[3] Control measurements were done in patched cells exposed to a stream of bath solution (140 mmol litre$^{-1}$ NaCl, 4 mmol litre$^{-1}$ KCl, 2 mmol litre$^{-1}$ Ca $Cl_2$, 1 mmol litre$^{-1}$ $MgCl_2$, pH 7.4, 284 mOsm). Thereafter, the same cells were exposed again to a stream of bath solution to which suxamethonium either 1 or 10 mmol was added. For steady-state activation (act) and inactivation (inact) the applied test pulses were plotted against normalized conductances. Boltzmann equations were fitted to the data yielding the voltage at half-maximum conductance ($V_{05}$) and the slope. Time constants for inactivation (τh) were obtained by bi-exponential fits to the decaying currents following voltage jumps from −100 mV to −30, −15, 0, 30 and 45 mV, respectively. Rate of recovery from inactivation at −100 mV was evaluated by a single exponential fit of normalized currents generated by test pulses to 0 mV which were plotted against the duration of the gap between 20 ms pre-pulses and test pulses to 0 mV. Statistic evaluation was performed by Wilcoxon and Mann-Whitney *U* test. $P<0.05$ was considered significant.

τh was significantly slower in R 1448H than in WT ($\bar{\tau}h_{R\ 1448H}=1.76$, range 1.2–2.35, $n=12$ *vs* $\bar{\tau}h_{WT}=0.45$, range 0.3–0.61, $n=11$ at 0 mV) with decreased voltage dependence of τh in R 1448H. In WT suxamethonium 1 mmol litre$^{-1}$ led to the following significant effects: shorter τh, left shift of $V_{05inact}$, left shift of $V_{05act}$ and enhanced maximum current. Besides a left shift of $V_{05inact}$ no significant effects of suxamethonium 10 mmol litre$^{-1}$ were found in WT. In R 1448H the same significant effects and, in addition, a delayed recovery were obtained only under suxamethonium 10 mmol litre$^{-1}$, whereas no significant effects of suxamethonium 1 mmol litre$^{-1}$ could be shown.

Our results confirmed recent reports[3] on marked electrophysiological differences between WT and R 1448H. These differences remained more or less unchanged by suxamethonium. The significant direct effects of suxamethonium found in this study were small, partly due to incomplete series resistance compensation and could not explain the above mentioned anaesthetic problems of patients suffering from hereditary sodium channel disorders. These were probably the result of depolarization itself.

## Effect of propofol on the uptake of propranolol into cultured cells

**D. J. Carter***, C. S Reilly and N. C. Bird*
*Department of Surgical and Anaesthetic Sciences, University of Sheffield*

The mechanism of action of anaesthetic agents remains largely unknown. However, there are a number of proposed mechanisms, and many of these involve nerve membranes and particularly ion channels or systems that regulate them.[1] It is thought that if the cell membrane or cell receptors were altered by anaesthetic agents, the uptake of other drugs into cells would be affected. This study was set up as a model for investigating this hypothesis, using propofol and the human neuroblastoma cell line SH-SY5Y. This established cell line expresses biochemical properties similar in characteristics to normal neuronal cells *in vivo*.[2] In this series of experiments, the model drug chosen was the lipophylic β adrenergic blocker, propranolol.

Cells of the human neuroblastoma cell line SH-SY5Y (passage 10-30) were cultured in Dulbecco's modified Eagle media (D-MEM) with 10% fetal calf serum, penicillin 100 IU ml$^{-1}$, streptomycin 50 μg ml$^{-1}$ and fungizone 25 μg ml$^{-1}$. Cells were fed twice weekly, and passaged with a 1:5 split ratio weekly. Cells became confluent after 7 days. Confluent cells were removed from T75 culture flasks and centrifuged to form a cell pellet. the cells were resuspended in 10 ml Hank's balanced salt solution (HBSS) without phenol red, and counted using the trypan blue exclusion method. The volume of media was adjusted to give $2\times10^6$ cells ml$^{-1}$.

One ml of cell suspension was aliquoted into 10 Eppendorf tubes. In the test group (five tubes), 10, 20 or 40 μl of 1 mmol litre$^{-1}$ propofol were added to each tube. In the control group (five tubes) 10, 20 or 40 μl of media were added to each tube. Cells were incubated in a waterbath at 37 °C for 10 min, after which 3H-propranolol 20 μl of 2 nmol litre$^{-1}$ (specific activity 25.0 Ci mmol$^{-1}$) was added to each tube. The tubes were incubated at 37 °C for 3 or 10 min, then centrifuged for 30 s in a microcentrifuge. The supernatant (incubation media) was removed and pellet was resuspended and washed in 1 ml of HBSS. The tubes were centrifuged for a further 30 s, and the supernatant (wash media) was removed. The cells were then resuspended in 1 ml HBSS. The incubation media, wash media and cell suspensions were transferred to scintillation vials, and 10 ml Optiphase 'Safe' added to each vial. Vials were inverted to ensure mixing of contents. All vials were then analysed on a Packard Tri-Carb Liquid Scintillation Counter, for 1 min. Each experiment (that is different volumes, different incubation times) was repeated 10 times.

The amount of 3H-propranolol in the cells was calculated as a percentage of 3H-propranolol in the media. The mean percentages of the 10 repeat experiments were calculated, and the means of the test and control data compared for all volumes of propofol and both 3H-propranolol incubation times. Results were compared using the Wilcoxon matched-pairs signed rank test.

Propofol appeared to inhibit the uptake of 3H-propranolol into cultured SH-SY5Y cells at all concentrations and incubations

*Table 12* Mean values and range for 3H-propranolol uptake (%) at the three concentrations of propofol after 3 and 10 min

| Volume of propofol (μl) | Control (range) | Test (range) | Difference | *P* value |
|---|---|---|---|---|
| 3 min | | | | |
| 10 | 40.2<br>(32.7–50.4) | 38.1<br>(26.3–49.1) | 2.1 | 0.0109 |
| 20 | 38.5<br>(30.1–49.2) | 35.3<br>(30.5–44.5) | 3.2 | 0.0125 |
| 40 | 37.6<br>(26.3–53.0) | 32.2<br>(22.1–43.0) | 5.4 | 0.0051 |
| 10 min | | | | |
| 10 | 39.8<br>(20.5–58.2) | 38.6<br>(20.1–57.2) | 1.2 | 0.0745 |
| 20 | 34.8<br>(26.0–42.9) | 30.7<br>(23.0–36.3) | 4.1 | 0.0051 |
| 40 | 37.5<br>(29.9–52.8) | 28.1<br>(17.3–41.8) | 9.4 | 0.0051 |

investigated (table 12). It also appeared that the inhibition is concentration-dependent.

The above method formed the basis of a model system to investigate the action of anaesthetic drugs on cells. From the results, it was not known how propofol inhibits the uptake of propranolol into the cultured cells. Further work using the same model will include using ion channel blockers and membrane perturbants to investigate if these agents have a similar effect on propofol uptake. Future experiments using this model might be useful for investigating the mechanisms of anaesthetic action.

### Only a small increase in end-expiratory pressure after cardiac surgery in Manchester

R. Fletcher and P. Foster*
*Department of Anaesthesia, Central Manchester Hospitals NHS Trust*

Significantly raised end-expiratory alveolar pressures (EEP) have been shown to be common after cardiac surgery in Sweden.[1] This study, done in Manchester, was designed to investigate the duration of this raised EEP after surgery. In the event, few patients developed clinically significant EEP. This paper compared and contrasted the present observations with the Swedish ones.

There were 24 patients, all undergoing cardiac surgery; 20 were male. The mean age was 60 (range 38–73) yr. EEP was measured by pressing the "expiratory pulse hold" button on the Servo 900C ventilator. Readings were made (1) before sternotomy and (2) after sternal closure. The ventilator was set to rate 10 min$^{-1}$, inspiratory and pause times 25 and 10% of cycle.

Mean EEP in Manchester was 1.1 cm $H_2O$ (range 0–8) before sternotomy, increasing non-significantly to 1.9 (0–12) cm $H_2O$ after sternal closure. In Sweden mean EEP was similar before sternotomy, 1.9 (0–12) cm $H_2O$, but significantly ($P<0.005$) greater after sternal closure: 5.2 (0–21) cm $H_2O$. Mean age, and mean $FEV_1$ and VC as percentages of predicted, did not differ between the two countries; however some details of the anaesthetic and cardiopulmonary bypass (CPB) management did (table 13).

*Table 13* Comparison of intraoperative regimes in the two centres

| | Sweden | Manchester |
|---|---|---|
| Pre-CPB fluids | None | 0.5–1 litre |
| Ventilatory gases | $O_2/N_2O$ | $O_2$/air/enflurane |
| Ventilatory rate | 20 min$^{-1}$ | 10 min$^{-1}$ |
| Ventilation during CPB | Tidal volume 200 ml<br>Rate 10 min$^{-1}$ | No ventilation |

What can have caused the much greater EEP values seen in Sweden? Ventilating during CPB causes the same increase in lung water as not ventilating.[2] End-expiratory resistance was only slightly greater at small tidal volumes than large.[3] But in clinically important EEP, expiratory flow did not approach zero asymptotically. Indeed, the time constants late in expiration when EEP was raised were so large—several seconds—that doubling expiratory time could make no meaningful difference to EEP.

**Key words**

Ventilation, airway pressure. Ventilation, positive end-expiratory pressure.

### Discriminating information in uncalibrated respiratory inductance plethysmography

A. Black, N. Habib, N. Goodman, C. O. Prys-Roberts*, J. Dixon and G. Kunst
*Sir Humphry Davy Department of Anaesthesia, University of Bristol*

Stable calibration of respiratory inductance plethysmography (RIP) cannot be guaranteed over the long periods required for clinical observation. We examined the information content of unreliably calibrated RIP by seeing see how well effects on breathing pattern of two different infusion rates of alfentanil could be distinguished.

Two groups of eight consenting women were assigned randomly to receive double-blinded postoperative infusions of alfentanil 5 or 20 μg kg$^{-1}$ h$^{-1}$ after routine abdominal hysterectomy under standardized general anaesthesia. They were cared for and studied in a 24-h recovery room until the first postoperative morning by personnel who did not know what dose rate of alfentanil was being infused. Escape analgesia was provided as pethidine 50 mg every 2 h as necessary.

The ribcage and abdominal RIP signals were subjected only to an initial multiple regression calibration. A BBC microcomputer made on-line estimates of breath-by-breath tidal volume (VT), inspiratory time (TI) and expiratory time (TE), and stored them as the record of breathing pattern.[1] The records lasted for between 14 and 17 h, and consisted of between 6 and 32 periods of reasonably stable breathing interspersed with periods of disturbed pattern associated with non-respiratory movements such as talking, coughing, moving and being moved. Occasional brief disturbances were edited from periods of otherwise quiet breathing without reference to the dose rate of alfentanil, and the remaining breaths in each period were used to calculate the average VT, TI and TE, their coefficients of variation (cvVT, cvTI and cvTE) and the correlation coefficients between VT and TI for that period. A grand average of each of these seven within-period features of the breathing pattern was calculated for the whole study period for each of the 16 patients. Selections of grand average features of random selections of the patients were used to try to distinguish whether the remaining patients had been receiving a low or high dose of alfentanil. The power of discrimination was checked against the expectations of chance discrimination as described by binomial distributions. The analyses used the DISCRIMINANT procedure in MINITAB (run on an ELONEX PC-4100 microcomputer).

The overall average VT was the best single discriminator, and multiple discriminant models that included VT as an absolute measurement were more robust than models that did not. The best overall performance was from a model using VT, cvTI and cvTE. Models made from the grand average of the seven features of any 15 patients could use the seven features available from any single period of quiet breathing of the 16th patient and thereby identify the alfentanil dose received by that patient more often than expected by chance, significantly so ($P<0.05$) for all but three patients.

**Key words**

Measurement techniques, multivariate analysis. Measurement techniques, inductance plethysmography.

### Effect of sevoflurane on spontaneous and evoked sympathetic activity in dogs

D. Ma*, C. Wang, C. K. Pac Soo*, M. K. Chakrabarti and J. G. Whitwam
*Department of Anaesthetics, Royal Postgraduate Medical School, Hammersmith Hospital, London*

A previous study has shown that desflurane at low concentrations causes a 30% increase in spontaneous sympathetic activity with

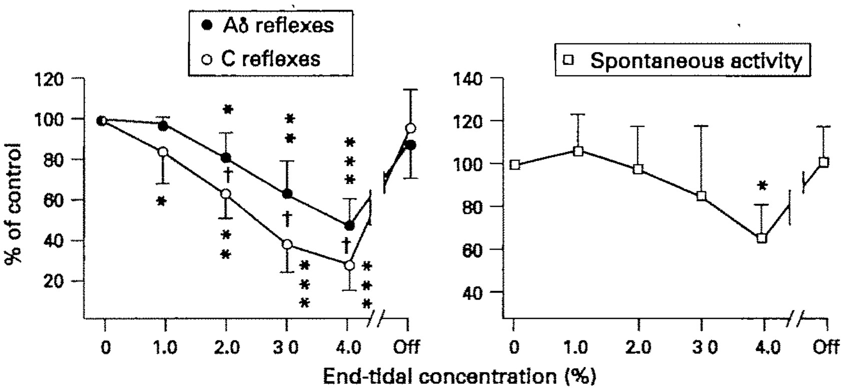

*Figure 17* Effect of sevoflurane on spontaneous and evoked sympathetic activity. Results are mean (SD) ($n$=5). Comparison with control: *$P<0.05$; **$P<0.01$; ***$P<0.001$. Comparison between Aδ and C reflexes: †$P<0.05$.

little depression of somatosympathetic reflexes. At higher concentrations, it depresses spontaneous and evoked sympathetic activity with a similar effect on Aδ and C responses. In contrast, isoflurane causes a dose-dependent depression in both spontaneous and evoked sympathetic responses with a relatively greater depression on C compared with Aδ reflexes.[1] This original observation has led to an ongoing study of the relative effects on sympathetic activity of the inhalational agents commonly in clinical use under similar conditions in the same animal model. The present study examined the effect of sevoflurane on spontaneous and evoked sympathetic activity in dogs and associated haemodynamic responses.

Experiments were carried out in five beagles anaesthetized (α-chloralose 15–20 mg kg$^{-1}$ h$^{-1}$), paralysed (suxamethonium 10 mg i.v. every 30 min) and artificially ventilated. Oesophageal temperature and blood gases were kept within the normal range. The radial and renal sympathetic nerves were exposed, desheathed, cut distally and mounted on silver electrodes in mineral oil pools. Supramaximal electrical stimuli (0.33 Hz, 50 V, 0.5 ms) were applied to the radial nerve. The evoked somatosympathetic reflexes were averaged, rectified and integrated. Spontaneous renal sympathetic discharges were amplified, rectified and integrated. Sevoflurane was administrated in each preparation to end-tidal concentrations of 1%, 2%, 3% and 4% for 20 min, respectively, after which measurements were recorded, and repeated 1 h after discontinuation of the agent.

Figure 17 shows the effect of sevoflurane on spontaneous and evoked sympathetic activity. It can be seen that at a 1% concentration there was no significant effect on Aδ reflexes but already C reflexes were depressed by 17% ($P<0.05$). By 4% the Aδ and C reflexes were 45.8% and 26.4% of control respectively ($P<0.01$). For spontaneous sympathetic activity there was no statistically significant decrease up to 3% but by 4% sevoflurane it was depressed to 64.1% of control ($P<0.05$).

Mean cardiac output remained unchanged up to 3% but decreased to 1.42 litre min$^{-1}$ from a control value of 1.64 litre min$^{-1}$ at 4% of sevoflurane ($P<0.05$). The mean MAP and systemic vascular resistance (SVR) markedly decreased in a dose-dependent manner from control values of 133 mm Hg and 6500 dyn s cm$^{-5}$ to 65 and 3654 at 4% sevoflurane respectively. The heart rate (HR) showed no significant decrease up to 3% but at 4% decreased to 132 beat min$^{-1}$ from the control value of 173 beat min$^{-1}$.

All variables returned to within control values after withdrawal of sevoflurane.

This study indicated that sevoflurane depressed Aδ- and C-fibre-mediated somatosympathetic reflexes in a dose-related manner, and that it had a greater effect on C compared with Aδ reflexes. At low concentrations it did not affect spontaneous sympathetic activity which was depressed significantly at higher concentrations. It decreased arterial pressure and SVR in a dose-dependent fashion and decreased cardiac output and HR at higher concentrations. There was no evidence of sympathetic excitation. The relative effect on C reflexes was greater than for isoflurane.[1]

## Association between inability to view the glottis at indirect laryngoscopy and difficult intubation: a preliminary assessment

G. KESSELL* AND J. E PEACOCK
*Department of Surgical and Anaesthetic Sciences, University of Sheffield*

The association between the glottis view at indirect laryngoscopy and degree of difficulty of tracheal intubation has not previously been investigated. The principal aim of this preliminary study was to examine a group of confirmed difficult intubations and a control group of easy intubations to assess whether or not inability to view the glottis at indirect laryngoscopy was associated with difficult intubation.

Anaesthetists of all grades were asked to refer any patient that was assessed preoperatively as a potentially difficult intubation (whether they proved to be difficult or not) and any patient that was found to be difficult to intubate (whether this was suspected or not). The details of the laryngoscopy findings and the degree of difficulty of intubation were not known to the investigator until after the patient had been examined postoperatively. A control group of patients requiring intubation was also assessed. The patients were examined for Mallampati grade (as modified by Samsoon and Young[1]), interdental distance, thyromental distance, restricted neck mobility, mandibular protrusion and glottic visibility on indirect laryngoscopy.

Thirty-six patients were referred, of which there were 22 difficult intubations and 14 that were assessed preoperatively as potentially difficult that were found to be easy intubations. Nineteen of the difficult intubations were difficult direct laryngoscopies (that is, Cormack and Lehane grades III or IV[2]) with three patients being grade II laryngoscopies that required multiple attempts before the trachea was successfully intubated. A further 22 control patients were examined all of which were grade I laryngoscopies. The following patient features were selected as potentially predictive of difficult intubation: Mallampati grades III and IV, thyromental distance ≤7 cm, interdental distance ≤3.2 cm (mean of our results − 1 SD), moderate or severe limitation of neck movement, inability to protrude the lower incisors anterior to the upper incisors and inability to view beyond the epiglottis on indirect laryngoscopy. The association between each predictive test and difficult intubation was examined using chi-square and Fisher's exact test (where indicated).

There were 14 patients in the original group of 36 referred patients who had features to suggest difficult intubation but were found to be easy intubations. For the two tests with acceptable detection rates, that is Mallampati and indirect laryngoscopy, the number of wrong "difficult" predictions were 11 and 4 respectively (table 14).

*Table 14* Comparison of the performance of each predictive test on the difficult intubation group and the control group

| | Difficult intubations ($n$=22) | Controls ($n$=22) | |
|---|---|---|---|
| Predictive test | No. detected | False positives | $P$ |
| Mallampati | 16 (73%) | 6 (27%) | <0.01 |
| Thyromental distance | 4 (18%) | 0 (0%) | 0.1 |
| Interdental distance | 8 (36%) | 1 (5%) | 0.02 |
| Jaw protrusion | 3 (14%) | 0 (0%) | 0.2 |
| Neck mobility | 6 (27%) | 1 (5%) | 0.1 |
| Indirect laryngoscopy | 15 (68%) | 0 (0%) | <0.001 |

The association between failure to see the glottis at indirect laryngoscopy and difficult intubation needs to be tested prospectively before its use as a predictor of difficult intubation can be advocated.

**Key words**
Intubation tracheal, difficult. Anaesthesia, evaluation, preoperative.

## Comparison of the immediate effects of induction of anaesthesia with etomidate, propofol and thiopentone on cerebral haemodynamics

A. T. LOVELL*, H. OWEN-REECE*, C. E. ELWELL*, M. SMITH AND J. C. GOLDSTONE*
*Departments of Academic Anaesthesia and Medical Physics, University College London Medical School, The Middlesex Hospital, London*

Most existing techniques of cerebral oxygenation monitoring are either invasive, require prolonged equilibration or involve ionizing radiation. Near infrared spectroscopy (NIRS) enables continuous non-invasive measurement of oxyhaemoglobin and deoxyhaemoglobin. Changes in cerebral metabolism and haemodynamics are known to occur after induction agent administration,[1] but their time course is difficult to study.

Thirty-six unpremedicated ASA grade I and II adult patients undergoing elective day-case surgery were studied. Oxyhaemoglobin and haemoglobin were recorded (Hamamatsu NIRO500) with an inter-optode spacing of 4 cm, with optodes located in the temporo-parietal region. The patients were allocated randomly to have anaesthesia induced with etomidate, propofol or thiopentone. Respiration was assisted as necessary to maintain normocapnia.

Areas under the concentration time curves of oxyhaemoglobin and haemoglobin were calculated to provide an index of changes in oxygenation of the brain against time. Groups were compared using a repeated measures ANOVA design, followed by $t$-tests with Bonferroni's correction.

After induction of anaesthesia, arterial saturation and end-tidal carbon dioxide did not significantly change. The area under the haemoglobin time curve did not significantly change either with respect to time ($P$=0.99) or induction agent ($P$=0.24) (table 15). The area under the oxyhaemoglobin time curve showed marked changes with respect to both time ($P$<0.001) and induction agent ($P$<0.001). Subgroup analysis showed that the decrease in oxyhaemoglobin seen in the etomidate group was significantly different from the increases seen with propofol ($P$<0.001) and thiopentone ($P$<0.001). The differences in oxyhaemoglobin between propofol and thiopentone were not significant.

*Table 15* Integrated oxyhaemoglobin and haemoglobin after induction of anaesthesia (mean (SD))

| | Etomidate | Propofol | Thiopentone |
|---|---|---|---|
| Haemoglobin ($\mu$mol litre$^{-1}$): | | | |
| 0–60 s | 0.44 (1.15) | −0.01 (0.72) | 0.26 (0.38) |
| 0–180 s | 0.81 (2.23) | 0.33 (4.68) | 0.82 (1.73) |
| Oxyhaemoglobin ($\mu$mol litre$^{-1}$): | | | |
| 0–60 s | −0.12 (2.05) | 0.32 (1.02) | 0.30 (1.09) |
| 0–180 s | −5.06 (6.89) | 9.27 (4.88) | 10.2 (10.0) |

This study showed that NIRS detected the small changes in oxygenation that occur during induction. These changes occurred within a time frame which only NIRS can detect at the bedside. The total amount of haemoglobin within the field of view is represented by the sum of haemoglobin and oxyhaemoglobin. Since haemoglobin remained unchanged, the changes in oxyhaemoglobin represented the change in total haemoglobin within the field. These changes occurred very shortly after loss of consciousness, at a time when no i.v. fluids were administered. Since the haematocrit would be expected to remain constant, it is likely that the change in the total haemoglobin signal was proportional to a change in the blood volume of the field of view. The increase in oxyhaemoglobin, at the same time as that in blood volume would suggest an increase in tissue oxygen saturation in the propofol and thiopentone groups. Similarly the decrease in oxyhaemoglobin in the etomidate group would suggest a decrease in tissue oxygen saturation.

**Key words**

## Blood gas changes during apnoeic oxygenation in infants and children

A. R WOLF
*Royal Hospital for Sick Children, Bristol*

Hypoxia develops rapidly during apnoea in young children breathing room air. A recent study in adults has demonstrated that stable gas exchange is achievable during continuous endobronchial insufflation of oxygen.[1] Given the lack of paediatric data, we determined to measure the changes in blood gas values of oxygen and carbon dioxide during apnoea after preoxygenation in small children.

After appropriate ethical consent, we studied 27 infants and children undergoing cardiac catheterization. Nineteen of the children were scheduled for PDA ligation and the others were known to have no major cardiac shunts. Anaesthesia was maintained with i.v. propofol infusion, fentanyl and pancuronium. At the end of the procedure, the patients were ventilated on 100% oxygen for 5 min down to an end-tidal carbon dioxide of 25 mm Hg. Ventilation was discontinued and the patient connected to a T-piece circuit with 1 litre min$^{-1}$ fresh gas flow. Blood gases were taken at 1-min intervals for 5 min and the study was abandoned if $P\text{CO}_2$ rose to 70 mm Hg, oxygen saturation decreased below 90% or the patient started to breathe.

Patients' ages ranged from 1 month to 13.3 years with a mean of 4.97 years. Five patients were less than 1 year old. Mean oxygen tension decreased from 557.4 (SD 83.7) mm Hg at the start of apnoea to 361.8 (94.5) mm Hg by 5 min. Most of the decrease in oxygen tension occurred during the first minute (103.9 (50.0) mm Hg). Carbon dioxide tension increased from 27.6 (3.1) mm Hg at the start of apnoea to 54.5 (10.7) mm Hg at the end of 5 min (fig 18). Surprisingly, the values for changes in blood gases during apnoea from this study are similar to the adult data: oxygen decrease after the 1st min averaged 11.3 mm Hg min$^{-1}$ [range 17–48.9] while the increase of carbon dioxide averaged 3.5 mm Hg min$^{-1}$ [range 1.6–7.5]. Only one patient needed

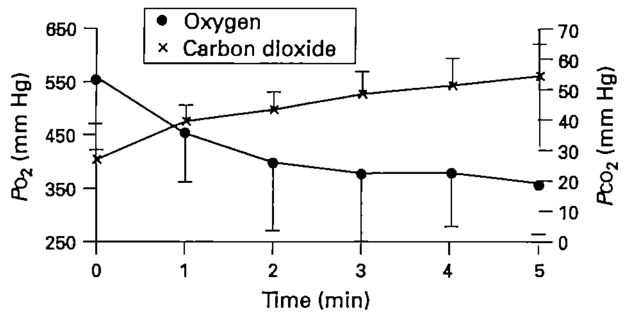

*Figure 18* Changes in blood gas values in children during apnoea after preoxygenation for 5 min. All values are means (SD).

to be withdrawn from the study because of decreasing oxygen saturation. There did not appear to be a relationship between age and changes in oxygen and carbon dioxide during apnoea.

## Interaction of lignocaine with recombinant opioid receptors expressed in Chinese hamster ovary cells

K. Hirota, B. L. Appadu, D. K. Grandy, L. A. Devi and D. G. Lambert
*University Department of Anaesthesia, LRI, Leicester and Vollum Institute, Portland, Oregon, USA and Department of Pharmacology, New York University Medical Center, NY, USA*

Local anaesthetics have been reported to enhance opioid analgesia.[1] However, it is still unknown whether local anaesthetics interact with opioid receptors. In this study, we examined the interaction of local anaesthetics with recombinant, μ, κ or δ opioid receptors expressed in Chinese hamster ovary (CHO) cells, (CHO-μ, κ or δ, respectively).

All studies were performed with membranes prepared in TRIS-HCl 50 mmol litre$^{-1}$, pH 7.4 by homogenization and centrifugation. Binding assays were performed in 1-ml volumes of TRIS-HCl 50 mmol litre$^{-1}$, pH 7.4, for 90 min at room temperature using approximately 200 μg of protein. Non-specific binding was defined in the presence of naloxone $10^{-5}$ mol litre$^{-1}$. Bound and free radioactivity were separated by vacuum filtration. In displacement studies, the interaction of lignocaine $10^{-6}$–$10^{-2}$ mol litre$^{-1}$ with μ, κ and δ-opioid receptors was determined by displacement of [$^3$H]diprenorphine 0.5 nmol litre$^{-1}$. Saturation analysis to determine the equilibrium dissociation constant (*K*d) and the maximal binding capacity (Bmax) of CHO-μ, κ or δ in the presence and absence of lignocaine were performed using increasing concentrations of [$^3$H]diprenorphine 0.03–3.0 nmol litre$^{-1}$. *B*max and *K*d were obtained from Scatchard plots. The concentration of lignocaine producing 50% displacement of specific binding ($IC_{50}$) were obtained by computer assisted curve fitting (GRAPHPAD-PRISM) and corrected for the competing mass of [$^3$H]diprenorphine according to Cheng and Prusoff[2] to yield the affinity constant (*K*i). All data were expressed as mean (SEM) ($n \geq 5$).

*Table 16* *K*d (pmol litre$^{-1}$) and *B*max (fmol mg$^{-1}$ protein) values for [$^3$H]diprenorphine binding to CHO-μ, κ or δ membranes in the absence and presence of lignocaine (*μ: $P$=0.0004, κ: $P$=0.0228, δ: $P$=0.0001 Student's *t*-test)

| | Bmax | *K*d |
|---|---|---|
| δ | 279 (4) | 372 (15) |
| +2.5 mmol litre$^{-1}$ lignocaine | 287 (3) | 674 (13)* |
| μ | 272 (3) | 85 (5) |
| +1.0 mmol litre$^{-1}$ lignocaine | 263 (6) | 209 (9)* |
| κ | 70 (2) | 91 (6) |
| +0.3 mmol litre$^{-1}$ lignocaine | 66 (3) | 167 (16)* |

[$^3$H]diprenorphine binding was dose dependent and saturable with *K*d (pmol litre$^{-1}$) and *B*max (fmol mg$^{-1}$ protein) values shown in table 16. Lignocaine dose-dependently displaced diprenorphine binding to all opioid receptors with the following rank order potency (p*K*i) κ (3.68 (0.02))>μ(3.26 (0.04))>δ (2.74 (0.03)) Lignocaine increased the *K*d of diprenorphine without affecting the *B*max, consistent with an allosteric interaction at opioid receptors. Further studies on the nature of the interaction and whether this could contribute to the reported analgesic effects[1] are currently under way in out laboratory.

## Oxygenator exhaust capnography as an index of arterial carbon dioxide tension during cardiopulmonary bypass employing a membrane oxygenator

M. J. O'Leary*, S. P. MacDonnell* and C. N. Ferguson
*Department of Anaesthetics, St Bartholomew's Hospital, London*

A previous report described the use of oxygenator exhaust capnography ($PE_{CO_2}$) as a monitoring technique during cardiopulmonary bypass employing a bubble oxygenator.[1] During the cooling and stable hypothermic phases of cardiopulmonary bypass the relationship with arterial carbon dioxide tension ($Pa_{CO_2}$) was reasonably accurate, but became far more variable during rewarming. We have investigated the relationship between $PE_{CO_2}$ and $Pa_{CO_2}$ during hypothermic cardiopulmonary bypass with non-pulsatile flow employing a membrane oxygenator.

Thirty-two patients undergoing cardiopulmonary bypass had oxygenator exhaust gases channelled into 100 cm of elephant tubing from the midpoint of which gases were sampled by a side-stream capnograph. Five min after institution of cardiopulmonary bypass and at 15-min intervals thereafter the capnograph reading was recorded and an arterial blood sample drawn for measurement of $Pa_{CO_2}$ by a bench blood gas analyser. An additional sample was drawn and measurement recorded at 34 °C during rewarming.

A total of 172 paired measurements were made. The degree of agreement between paired measurements ($Pa_{CO_2}$ and $PE_{CO_2}$) at each time point was calculated using the method of Bland and Altman[2] (fig 19).

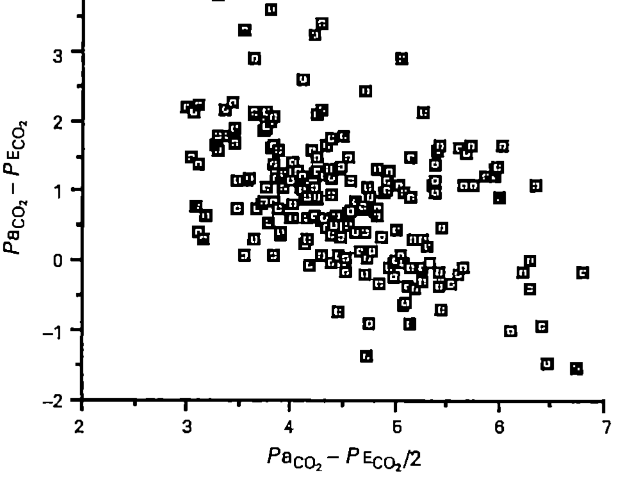

*Figure 19* Relationship between the difference between measurements (y axis) and the mean of the measurements (x axis) at each time point (all measurements).

Mean difference was 0.9 kPa (d) with a standard deviation of 0.99 kPa (s) (95% limits of agreement −1.09 to 2.88 kPa (L)). Results were further analysed during stable hypothermia (n=30, d=1.88, s=0 69, L=0 5 to 3.26), rewarming at 34°C (n=32, d=0, s=0.84, L=−1.28 to 1.28), rewarming at normothermia (n=48, d=0.15, s=0.69, L=−1.23 to 1.53) and with (n=78, d=0.62, s=0.99, L=−1.36 to 2.6) or without (n=91, d=1.07, s=0.9, L=−0.91 to 2.88) carbon dioxide running. No relationship was detected between either $Pa_{CO_2}$ or $PE_{CO_2}$ and core body temperature, pump blood flow or oxygenator gas flow.

We found no useful relationship between carbon dioxide concentration in exhaust gases from a membrane oxygenator during cardiopulmonary bypass and $Pa_{CO_2}$.

## Intraoperative gut hypoperfusion may be a risk factor for postoperative nausea and vomiting

Sir,—We read with interest the article on nausea and vomiting after cardiac surgery by Grebenik and Allman.[1] There are two issues which we believe are important but were not discussed by the authors.

Gut mucosal hypoperfusion is common after cardiac surgery and may be another factor that explains the high associated incidence of postoperative nausea and vomiting.[2] Animal studies have shown that damage to the gut is accompanied by an increase in 5-HT$_3$ in gut mucosa.[3] Radioligand binding studies demonstrated the presence of large number of 5-HT$_3$ receptors on vagal terminals that innervate the intestinal mucosa and on the same vagal afferent nerves located in the brain stem vomiting centre.[3] Furthermore, it has been demonstrated recently that plasma volume expansion during cardiac surgery is associated with maintenance of gut perfusion and reduction in postoperative morbidity, including persistent nausea and vomiting.[4]

The authors mentioned that "if the patients did not meet the criteria for tracheal extubation and required sedation to tolerate intubation and ventilation, an infusion of propofol 1–4 mg kg$^{-1}$ h$^{-1}$ was commenced until another trial of spontaneous breathing was performed at the discretion of the nursing staff" Propofol is an antiemetic in its own right. Numerous studies have shown that propofol as a primary agent for maintenance of anaesthesia was associated with a lower incidence of postoperative nausea and vomiting.[5,6] When used in this manner, it is more efficacious than ondansetron 4 mg.[7] We have defined plasma concentrations of propofol for effective treatment of PONV as 405 ng ml$^{-1}$ (95% confidence interval 280–530 ng ml$^{-1}$).[8] Data from computer simulation using the pharmacokinetic variables of Gepts and colleagues[9] demonstrated that infusion of propofol 1–4 mg kg$^{-1}$ h$^{-1}$ for sedation, as used by the authors, produces plasma propofol concentrations in the effective range for treatment of nausea and vomiting for up to 180 min after termination of infusion (fig. 1). However, they did not provide information on the number of patients treated with propofol and the duration and dose of propofol used in each group, which may affect the overall results.

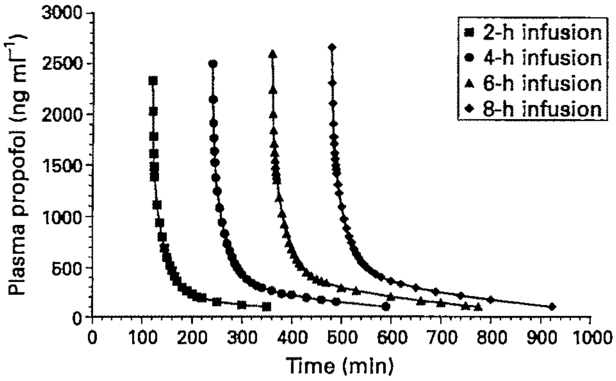

*Figure 1* Simulated plasma decay of propofol concentrations after 2-, 4-, 6- and 8-h infusions.

Hence it is important to specify the details of propofol administration in studies that investigate the incidence of PONV.

Sir,—Thank you for the opportunity to respond to the comments of Gan, Mythen and Glass. While gut mucosal hypoperfusion may be among the factors that are associated with postoperative nausea and vomiting (PONV), I would guess that this is not confined to cardiac operations and may well contribute to PONV after other types of major surgery.

Propofol undoubtedly possesses antiemetic properties. All our patients received an infusion of propofol during cardiopulmonary bypass. Patients whose tracheas were extubated immediately after return to the recovery unit would still have had propofol concentrations in the effective range for treatment of PONV at the time of tracheal extubation. Similarly, those patients who required a period of propofol sedation after operation would also have had therapeutic concentrations at tracheal extubation. We did not measure the amounts of propofol given, but duration of intubation did not differ significantly between our two groups. Given the large number of patients in each group ($n=200$ and $n=198$) it seems likely that the amounts of propofol given were similar in each group. Thus while propofol used either during anaesthesia or in the early postoperative period may have exerted an antiemetic effect during the first 2 h after tracheal extubation, this does not alter our findings that addition of droperidol to a continuous infusion of morphine was effective in reducing nausea and vomiting after cardiac surgery.

## Ethanol monitoring during hysteroscopy

Sir,—The complications of endometrial resection were reviewed by Williamson and Mushambi in an editorial in the September issue of *British Journal of Anaesthesia*.[1] The importance of fluid absorption in this context is emphasized by the fact that several fatal cases of the "female TUR syndrome" have occurred.[2,3] In their article, the authors did not recommend the ethanol method for monitoring fluid absorption because they could not account for the sex-related differences in breath ethanol and serum sodium responses to fluid absorption that were described by me in a recent review article.[4]

I have stated that the ethanol response to fluid absorption is 10% greater in middle-aged women undergoing endometrial resection than in elderly men undergoing transurethral resection of the prostate. This difference is easy to account for as most women are of a smaller size than men. The authors' distrust, however, was probably elicited by my suggestion that the serum sodium response to fluid absorption is 40% greater in females than in males. The magnitude of this difference can be illustrated by assuming that 1000 ml of irrigating fluid containing 1.5% glycine with 1% ethanol is absorbed by a male and a female. My nomograms suggest the reduction in serum sodium concentrations would amount to 8 mmol litre$^{-1}$ in males and 11 mmol litre$^{-1}$ in females.[4] Is this difference reasonable? Yes, I think so. The amount of extracellular water in the extracellular space, which is the distribution volume for sodium, has been reported to be 200 ml/kg body weight in males and 150 ml/kg body weight in women.[5] Based on these data, the difference that I have reported is what would be expected.

I admit that in the original study of fluid absorption by myself and Olsson, 62 patients were too few in number to allow construction of a nomogram.[6] However, as stated in my review article, the published nomogram was also based on a series of additional patients (up to a total of 70) who actually absorbed irrigating fluid. One of the additional cases has been described to show the elegance with which the ethanol method works.[7]

The "fluid deficit" is suggested in this editorial to be the best indicator of fluid absorption during hysteroscopy. This implies routine use of volumetric fluid balance. However, many factors need to be controlled to make routine use of this method accurate.[4] To my knowledge, its sensitivity has never been tested. Poor correlations between key variables which should all reflect fluid absorption are usually reported in studies where the method seems to have been used on a routine basis. My group has had difficulty obtaining useful data with it during prostatectomy.[8] The fluid deficit needs to be compared with more precise methods of measuring fluid absorption before I would recommend it as a standard method. As far as ethanol monitoring is concerned, several such studies have been conducted and its accuracy and precision are well known.

Sir,—We thank Professor Hahn for his interest in our editorial on complications of hysteroscopic treatments of menorrhagia,[1] and we are grateful for his comments.

It was not the aim of our editorial to exclude the ethanol method for estimating fluid absorption during transcervical endometrial resection (TCER). As stated by Professor Hahn both in his letter and in his review,[2] the nomograms for estimating fluid absorption from expired ethanol concentration during TCER were based on few patients. Incidentally, his review article stated that the TCER nomograms were based "on 62 patients with the addition of a few more patients with large scale absorption". Therefore, while the method has been investigated and used extensively during transurethral resection of the prostrate (TURP) we feel that more research and experience is necessary before we can recommend it for routine use during TCER. There is no doubt that, despite its limitations, volumetric fluid balance is still the most commonly used method of assessing fluid absorption during TCER. We agree with Professor Hahn that ethanol monitoring is a non-invasive, easy and accurate method of assessing fluid absorption during TURP. Hopefully in the near future this will also be applicable to its use during TCER.

## ACE inhibitors and renal protection

Sir,—I read with interest the article by Licker and co-workers[1] and agree that angiotensin converting enzyme (ACE) inhibitors may be of some value in renal protection during surgery. In a previous study we found that aortic cross-clamping-induced haemodynamic changes were less marked in enalapril-treated patients compared with controls,[2] in agreement with the study of Licker and colleagues. However, regarding renal perfusion, we established that effective renal plasma flow (ERPF) and glomerular filtration rate (GFR) were not maintained at baseline levels during aortic cross-clamping in enalapril-treated patients, although ERPF and GFR were good before clamping.[2] Licker and colleagues established that ACE inhibitors were effective in improving renal perfusion during aortic abdominal surgery and this seems to refute our own conclusions. In fact, these differences may be explained easily.

Their renal haemodynamic studies showed that aortic cross-clamping induced a significant decrease in ERPF in controls only (approximately −21%). However, although this decrease in ERPF in enalapril-treated patients was not statistically significant (approximately −14%), the renal blood flow:cardiac output ratio decreased significantly only in enalapril-treated patients (−25%); this strongly suggests that blood flow was redistributed away from the kidney during clamping. Moreover, although not statistically significant (but the number of enalapril-treated patients was small), the mean increase in renal vascular resistance and mean decrease in GFR during aortic cross-clamping (+43% and −20%, respectively) were not less relevant than the decrease in ERPF in controls. The data may have been confusing therefore because the threshold of statistical significance was not reached because of the small number of patients studied. Moreover, patients had different pathologies, notably both aortic aneurysm and atherosclerotic occlusive disease.

In my opinion, Licker and colleagues cannot assert that, in contrast with calcium antagonists,[2] ACE inhibitors prevent the renal vasoconstrictive effect of infrarenal aortic abdominal cross-clamping. Nevertheless, I agree that ACE inhibitors may boost renal perfusion before and after aortic clamping.

2. Colson P, Ribstein J, Seguin JR, Marty-Ane C, Roquefeuil B. Mechanisms of renal hemodynamic impairment during infrarenal aortic cross-clamping. *Anesthesia and Analgesia* 1992; 75: 18–23.

Sir,—We thank Dr Colson for his comments. We acknowledge that the small sample size of the study precludes firm conclusions concerning the haemodynamic changes induced by renin–angiotensin system block. The numbers of patients whose renal data were evaluated were nine and 11 for the saline and enalapril groups, respectively. At $P<0.05$ this number of patients was sufficient to detect a significant decrease in ERPF from a mean value of 472 to 371 ml $min^{-1}$ after aortic cross-clamping in the saline group whereas the (ns) changes observed in the enalapril group (from 582 to 499 ml $min^{-1}$) may represent a type II error. If we assume similar ERPF values in larger groups ($n=69$), "true differences" would have been reached for (within and between) group comparisons while maintaining a power of 0.90 ($\beta=0.10$); such data would confirm lesser impairment of renal haemodynamic state after pretreatment with enalapril.

During aortic cross-clamping, the renal blood flow:cardiac output ratio (RBF:CO) decreased by 25% in enalapril-treated patients and this was attributed entirely to a decrease in RBF as there was no change in CO. In contrast, proportional changes in RBF and CO were observed in saline-treated patients resulting in an unchanged RBF:CO ratio. Activation of unblocked vasopressor support systems (such as arginine vasopressin and the sympathetic nervous system) in response to aortic clamping could be implicated in the renal vasoconstriction in the two groups. In addition, the systemic haemodynamic pattern suggested that enalapril-induced vasodilatation was effective in renal and extrarenal vascular tissues; these data agree with experimental data supporting the notion that the splanchnic vascular bed is more sensitive to the vasoconstrictor effects of sympathetic stimulation and angiotensin II.[1 2]

The beneficial renal haemodynamic effects of enalapril were demonstrated clearly in the present study as: (1) the RBF:CO ratio increased before aortic cross-clamping as a result of a greater increase in RBF compared with CO, (2) during aortic clamping, ERPF was reduced to a lesser extent, (3) a greater glomerular filtration rate (GFR) was maintained; GFR and ERPF were strongly associated ($r=0.65$ in the enalapril group) after aortic clamping, implying that approximately 40% of the observed changes in GFR could be explained by haemodynamic variability.

Taken together, our preliminary data suggest lesser impairment of renal perfusion and function during aortic abdominal surgery after enalapril pretreatment.

## Possible mechanism to explain increased coagulability of blood after haemodilution

Sir,—We read with interest the discussion ensuing from the article by Ruttman, James and Viljoen[1] on hypercoagulability of blood after administration of i.v. crystalloids. Farmery and Kong[2] suggested that the results "challenge intuitive assumptions". We suggest that an increase in coagulability is reasonable for the following reasons. Blood coagulation is controlled by continuous interaction between pro- and anticoagulant factors. Haemodilution reduces the concentration of anticoagulant factors as much as procoagulant factors. Thus there is no intuitive reason to assume that anticoagulation would occur any more than procoagulation. A procoagulant effect could easily be brought about if the concentration–effect relationship of the anticoagulant factors were initially steeper than that of the procoagulant factors, that is dilution reduces the effect of anticoagulant factors more rapidly than procoagulant factors. This makes sense teleologically, where coagulability should increase after haemorrhage when blood volume is re-expanded with interstitial fluid.

As pointed out by the above authors, regional anaesthesia reduces the incidence of deep vein thrombosis despite the likely need for increased crystalloid administration. A possible explanation is that regional anaesthesia reduces the surgical stress response and its associated procoagulant effects. Could it be that crystalloid "primes" the coagulation system by the above proposed mechanism, and that the procoagulant tendency is then activated by surgical stress? We feel that these considerations would explain the observations reported, although we accept that evidence to confirm or refute them is not yet available.

2. Farmery AD, Kong A. Hypercoagulability induced by crystalloids. *British Journal of Anaesthesia* 1996; 77: 132.

Sir,—We thank Fletcher and Heard for their comment on our article. The argument they make that anticoagulant factors are diluted to the same degree as procoagulant factors is valid, and has been suggested previously by Monkhouse,[1] who suggested that haemodilution may disturb the ratio of thrombin to antithrombin III. An imbalance between the two may predispose to a procoagulant effect. Subsequent *in vivo* data, which are currently under consideration for publication, suggest that antithrombin III is decreased to a greater extent after haemodilution than could be explained by haemodilution alone, the inference being that the act of haemodilution *per se*, had induced the conversion of prothrombin to thrombin with subsequent thrombin–antithrombin III interaction. The suggestion by Fletcher and Heard that this effect may have a teleological basis is particularly elegant, as it could explain the reason for its occurrence.

## Regional anaesthesia in moyamoya disease

Sir,—We have read the article of Ngan Kee and Gomersall on extradural anaesthesia for Caesarean section in a patient with moyamoya disease.[1] We wish to describe our own experience with an elective Caesarean section managed with spinal anaesthesia in a patient with moyamoya disease.

A 34-yr-old woman suffered intraventricular bleeding in her 24th week of pregnancy, requiring intensive care and mechanical ventilation for 8 days. During this period the only unusual problem was development of pneumonia. She recovered without any sequelae and moyamoya disease was diagnosed by arteriography. The patient remained healthy for the remainder of the pregnancy and in the 38th week an elective Caesarean section was planned. Preoperative investigations were normal, including anticardiolipin antibody concentrations. After a preload of 1000 ml of lactated Ringer's solution, a left radial artery cannula and central venous catheter (via the antecubital fossa) were inserted under local anaesthesia. Analysis of arterial blood was carried out at 15-min intervals. Anaesthesia was performed with 0.5% spinal bupivacaine 15 mg and fentanyl 50 μg at L2–3, using a 25-gauge Whitacre needle, and 28% oxygen was given by face mask. The level of sensory analgesia to pinprick was T5. Total intraoperative fluid given was 1500 ml of mild lactated Ringer's solution. There were no changes in heart rate, direct arterial pressure or temperature, apart from transient hypotension (80% of preoperative value) treated with ephedrine 15 mg i.v. A healthy 3250-g male baby was delivered with Apgar scores of 8 (1 min) and 9 (5 min).

After surgery the patient remained in the PACU for 6 h and was discharged uneventfully without any change in her neurological status. There were no other problems in the subsequent 3 months.

Several cases have been reported of patients with moyamoya disease managed successfully with general anaesthesia for Caesarean section.[2] In our opinion, regional anaesthesia is preferable for these patients in order to obviate intubation-induced hypertension and the risk of aspiration. Some cases have also been reported using extradural anaesthesia.[3] However, the complication rate is less with spinal anaesthesia.[4] We believe that avoidance of hypotension, or treating it carefully, allows the use of spinal anaesthesia in these cases. By avoiding hypotension, hypothermia and hyperventilation, there were no neurological signs in our awake patient whose conscious state and cerebral function could be observed continually. A case of convulsions after spinal anaesthesia in a child with moyamoya disease has been reported,[5] probably caused by changes in cerebral blood flow (CBF). We believe that these convulsions occur more frequently in younger patients with moyamoya disease and may be avoided by strict management of CBF. The doses of bupivacaine used for extradural anaesthesia are higher than those used in spinal anaesthesia, with increased risk of neurological and cardiological problems.

Sir,—Thank you for the opportunity to reply to Drs Llorente de la Fuente, Gimenez Garcia and Lopez Sanchez. Although they have described the successful use of spinal anaesthesia for Caesarean section in a patient with moyamoya disease, we believe this is not the optimum technique in this circumstance. While we concur that regional anaesthesia has advantages over general anaesthesia, we believe that extradural anaesthesia is preferable to spinal anaesthesia.[1] Llorente de la Fuente, Gimenez Garcia and Lopez Sanchez have emphasized the importance of strict management of cerebral blood flow in these patients. We sought to achieve this by inducing central neural block gradually under close monitoring; we believe the slower onset of sympathetic block in extradural anaesthesia is more amenable to accurate titration of interventions compared with spinal anaesthesia.[2]

# Converting pH and H$^+$: a "rule of thumb"

Sir,—Many centres have changed to the use of hydrogen ion concentration (H$^+$) rather than the traditional pH when dealing with acid–base problems. Converting H$^+$ to pH or vice versa is very simple when tables are available. We propose a straightforward method for conversion when they are not.

We have observed that, between pH values of 7.10 and 7.60, the sum of the hydrogen ion concentration (in nmol litre$^{-1}$) and the numerical value of the two digits after the pH decimal point is relatively fixed around 83, the mean of these sums in this pH range (table 1).

*Table 1* Method for conversion of H$^+$ to pH

| pH | 7.00 | 7.10 | 7.20 | 7.30 | 7.40 | 7.50 | 7.60 | 7.70 |
|---|---|---|---|---|---|---|---|---|
| H$^+$ | 100 | 79.4 | 63.1 | 50.1 | 40 | 31.6 | 25.1 | 20 |
| Sum | 100 | 89.4 | 83.1 | 80.1 | 80 | 81.6 | 85.1 | 90 |

To convert pH from H$^+$, the numerical value of the two digits after the pH decimal point is calculated by subtracting H$^+$ from 83. For example, if H$^+$ is 70.8 nmol litre$^{-1}$, the estimated value of pH would be (7.83−70.8), or 7.12. The actual pH value at this hydrogen ion concentration is 7.15.

To convert H$^+$ from pH, the numerical value of the two digits after the pH decimal point is subtracted from 83. Therefore, if pH is 7.50, the estimated value of H$^+$ would be 83−50, or 33 nmol litre$^{-1}$. The actual hydrogen ion concentration at this pH is 31.6 nmol litre$^{-1}$.

The errors are small and clinically inconsequential for conversions performed between pH values of 7.10 and 7.60. We feel that our simple "rule of thumb" will be useful to doctors dealing regularly with clinical situations in which acid–base disturbances are a feature.

# Local anaesthesia to the airway reduces sedation requirements in patients undergoing artificial ventilation

Sir,—We read the article of Mallick, Smith and Bodenham[1] with interest and wish to make a few comments. In their study, although the use of local anaesthetic solution reduced the need for sedation in patients who underwent ventilation, it also suppressed the cough reflex. Patients appeared to be less bothered by pulmonary suctioning. The technique may be safe if used for short periods but our concern is that, if used over a longer period it may increase the risk of pulmonary infection.

Mucociliary clearance is an important mechanism of pulmonary defence. Effective mucociliary clearance depends on the function of the cilia and their coordinated beating.[2] Corssen and Allen[3] studied ciliary function in tracheobronchial epithelium obtained with a punch biopsy and found that lignocaine caused a dose-related but reversible effect on ciliary activity. At low doses ciliary beating was stimulated and as the dose increased the cilia stopped beating. In contrast, amethocaine and cinchocaine caused irreversible stoppage of ciliary activity. It is clear that topical anaesthesia may cause areas of ciliary dysfunction and could predispose to airway colonization and pneumonia. The effects of long-term local anaesthesia on ciliary motility have not been studied.

We believe that further studies are needed to evaluate the effect of local anaesthetics on respiratory epithelium. One suggestion is to compare the effect of local anaesthetics on mucociliary clearance using either a dye or a radio-opaque contrast as a marker. If the use of topical anaesthesia is found to be safe, then reduced requirements for sedatives may prove beneficial and may reduce the morbidity and mortality of patients undergoing artificial ventilation.

## Anticholinesterases and subsequent duration of block of suxamethonium

Sir,—I read with interest the article by Fleming and colleagues[1] on the effects of anticholinesterases on subsequent duration of block with suxamethonium. The clinical observations are clear and in accord with conventional wisdom.

The authors have however fallen into a common trap with regard to their interpretation of the cholinesterase activity values. Their pooled data are in accord with those of Viby-Mogensen,[2] who they referenced, in that over the clinical range the correlation between measured activity and duration of suxamethonium block is poor. In this study, a correlation can be shown clearly only in the presence of extremely low levels of measured activity. Another part of the problem is that the substrate used is not that used clinically (suxamethonium) but a thiocholine derivative, and that the correlation between different assay techniques and suxamethonium sensitivity is less than ideal.[3]

In addition, although not stated by the authors, such measurements of cholinesterase activity involve a large dilution of the plasma sample; this varies between laboratories but is usually 30–300-fold dilution into the reaction mixture. For cholinesterase inhibitors with prolonged covalent binding such as neostigmine, any inhibition produced would be likely to persist over a short period of dilution. Neostigmine concentrations decrease rapidly *in vivo* to approximately $6 \times 10^{-7}$ mol litre$^{-1}$.[4] This concentration is associated with approximately 50% inhibition of cholinesterase activity (unpublished personal data, see fig. 1) and accords with the authors observations. Other less tightly bound agents such as edrophonium[5] would be expected to be associated after such dilution with a lower inhibition than might be predicted from plasma concentrations at the time of sampling. The assumption that enzyme inhibition measured after dilution *ex vivo* accurately reflects *in vivo* conditions is a common but erroneous one.

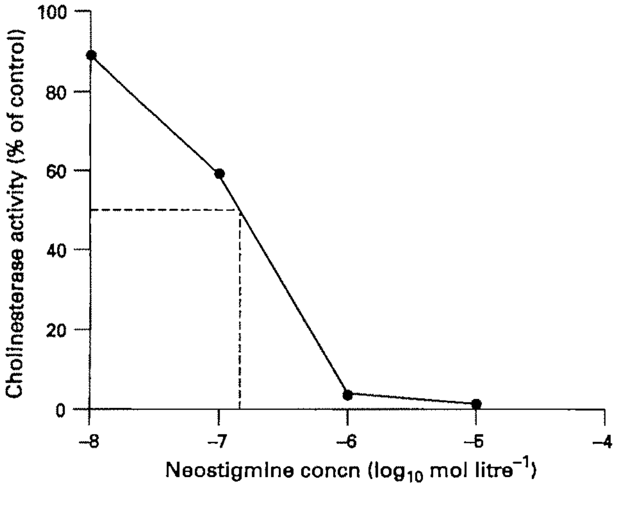

*Figure 1* Effects of neostigmine on plasma cholinesterase catalysis. Data are means of repeated measures of plasma from a normal individual. The assay is a modification of that of Ellman and colleagues.[6]

Sir,—We thank Dr Graham for his interest in our work and appreciate the opportunity to respond to his comments. Although we beg to differ as to whether the interpretation of our results constitutes "falling into a common trap", we feel his letter highlights some limits of our studies and emphasizes aspects of this work which could benefit from further discussion.

We agree that although Viby-Mogensen described the most commonly referenced relationship between measured activity of plasma cholinesterase and the duration of action of suxamethonium,[1] when cholinesterase activity is in the normal clinical range, the slope of this graph is indeed shallow. The hyperbolic relationship he plots is largely determined by values outside the normal range. Although the sensitivity of the plasma cholinesterase activity assay for detection of less active variants of the enzyme may be improved slightly by the use of alternative substrates as described by Evans and Wroe,[2] their study focuses on the detection of less active variants of the plasma cholinesterase enzyme, not on the characteristics of normal enzyme which has been exposed to a cholinesterase inhibitor. It is the effects of the mechanism of inhibition which we believe deserve emphasis.

As non-competitive inhibitors which react to form a carbomoylated cholinesterase enzyme, neostigmine and pyridostigmine are unlikely to be affected by assay techniques which include a dilutional step. In contrast, edrophonium, as a competitive inhibitor, may be profoundly affected. This may explain the contrast between studies which demonstrate minimal inhibition of plasma cholinesterase activity by edrophonium[3 4] while the metabolism of other substrates (e.g. mivacurium) is inhibited.[4]

For non-competitive inhibitors, dilutional effects on enzyme activity measurements should be at best, minimal, and at worst, comparable. There is no evidence that the substrate used for the assay should have a differential sensitivity for these chemically related inhibitors. In our studies, pyridostigmine produced profound inhibition of plasma cholinesterase (79% of baseline) compared with neostigmine (48% of baseline). In contrast, the duration of action of suxamethonium increased only 35% after pyridostigmine compared with 78% after neostigmine. Despite the limitations of the enzyme activity assay, we believe this contrast provides the strongest evidence that this is a much more complex drug interaction than previously realized.

## I.v. anaesthetics and binding to calcium channels

Sir,—The article by Hirota and Lambert[1] demonstrating an interaction between a variety of i.v. agents and the dihydropyridine binding site on L-type voltage-sensitive $Ca^{2+}$ channels is an interesting addition to the bewildering literature on mechanisms of anaesthesia.

The concept that i.v. anaesthetic agents may reduce neurotransmitter release via diminished influx of calcium ions is attractive as calcium influx is the common trigger for neurotransmitter release in invertebrates and vertebrates.

The authors hypothesize that i.v. anaesthetics may act via inhibition of calcium influx through L-type channels. Although their discussion may appear convincing, there are reservations with this hypothesis.

First, L-type channels do not seem to be crucial to stimulus–secretion coupling in the majority of vertebrate preparation studied[2–5] as this coupling is generally insensitive to dihydropyridine antagonists. If the likely target for anaesthetics is transmission across central synapses, then the significance of L-type calcium channel inhibition for anaesthesia may be minimal. Interestingly, other calcium channels, for example P and N channels, have been implicated in neurotransmitter release in vertebrate neurones.[3,4]

Second, are the authors, therefore, observing non-specific actions of anaesthetic agents rather than actions which underlie anaesthesia? Stereospecific differences in anaesthetic effects are seen at the receptor level for isoflurane on the $GABA_A$ receptor.[6] Hypnosis may also be stereospecific.[7]

Although it is perhaps too early to say if stereospecificity may be a marker for actions that are relevant to the mechanism of anaesthesia, it is worthy of note that the anaesthetic effects of isoflurane on L-type calcium channels do not demonstrate stereoselectivity.[8,9]

Third, the overwhelming fact remains that traditional dihydropyridine antagonists have minimal action as anaesthetics in the conventional sense, even if the blood–brain barrier is crossed.

I believe that these considerations significantly weaken the case for inhibition of calcium influx in L-type channels being an important mechanism of action of i.v. anaesthetic agents.

Sir,—We thank Dr Wilkinson for his interest and comments on our article.[1]

Before we respond to his detailed comments we wish to state clearly our position. We are not totally convinced that voltage-sensitive $Ca^{2+}$ channels (VSCC) have a role to play in anaesthesia but we are equally not convinced that they do not. We feel that it is premature to exclude this important class of ion channels as anaesthetic target sites and hoped that this is what our article and a recent editorial[2] conveyed. We agree that the literature is bewildering but as Dr Wilkinson points out, inhibition of VSCC and hence neurotransmission is an attractive site for anaesthetic action.

While our article was concerned specifically with L channels (probed using the radiolabelled dihydropyridine $[^3H]$PN200-110) we do not exclude other types of VSCC, such as P and N channels, as target sites for anaesthetic agents and this was also noted in our recent editorial.[2] Indeed, studies with radiolabelled conotoxin (specific for N channels) are currently at the planning stage. Dr Wilkinson cites several studies that show neurotransmitter release is not controlled by L channels and in general we agree with this. However, there are reports showing that L channels are involved (see Spedding and Lepagnol[3]). Of particular interest to us is the SH-SY5Y human neuroblastoma cell line that we have used in several studies of the mechanism of action of i.v. and volatile general anaesthetic agents. In this cell line L channel-mediated noradrenaline release and $K^+$-evoked increase in $[Ca^{2+}]_i$ are inhibited by thiopentone, propofol, ketamine, etomidate and halothane.[4–7] Moreover, we feel that modulation, by classic L channel agonists and antagonists, of ethanol, barbiturate and benzodiazepine potency[8,9] indicates something important! In addition, L-VSCC blockers have antinociceptive actions which are known to contribute to anaesthesia.[10–13]

There is strong support for the $GABA_A$ receptor as a target site for anaesthetic agents[14] and we have never disputed this fact. Stereoselectivity is noted for the $GABA_A$ receptor for a range of resolved anaesthetic agents. However, as Dr Wilkinson points out "it is perhaps too early to say whether stereospecificity may be a marker for actions that are relevant to the mechanism of anaesthesia".

The point made regarding the "non-anaesthetic" effect of L channel antagonists is well taken but it still remains that in experimental animals L channel agonists and antagonists modify ethanol, barbiturate and benzodiazepine potency.[8,9] In addition, Nacif-Coelho and colleagues reported that direct administration of L channel ligands into the locus coerulus modified the anaesthetic potency of dexmedetomidine in the rat.[15] Collectively, these data suggest that provided passage of the blood–brain barrier is facilitated, L channel blockers can have "anaesthetic-like" effects.

In summary, our studies with L channels form a basis for further studies with N and P channels and we feel that it is premature to exclude the voltage-sensitive $Ca^{2+}$ channel as a target site for anaesthetic agents.

# BOOK REVIEWS

*Pain Relief and Anesthesia in Obstetrics.* A. VAN ZUNDERT AND G. W. OSTHEIMER. Published by Churchill Livingstone, New York. Pp. 1062; indexed; illustrated. Price £100.00.

This book comprises 101 chapters set out in seven sections, with contributions from 179 authors, mainly from the USA, but some from Europe, Scandinavia, South America, Australia, New Zealand, Canada and Lebanon. Most chapters give the views of authors from more than one continent, often giving American and European perspectives.

Following an introduction by two well known obstetric anaesthetists (G. Marx and P. R. Bromage) and a brief history of pain relief in childbirth, the first section covers physiological and pharmacological influences in the mother, fetus and neonate. Chapters in this section are well written and illustrated. However, the chapter on maternal assessment gave a European view which may not be a true representation of clinical practice in the UK and possibly Europe. I find it hard to believe that most European obstetric anaesthetists warn patients about the occurrence of Homer's syndrome as a complication of extradural analgesia. This chapter also states that a woman in labour may be denied extradural analgesia if she has not attended a prepartum consultation, unless the obstetrician makes a personal request on clinical grounds.

The second section covers extradural analgesia for obstetric pain relief. It includes anatomy of the spine and pharmacology of drugs used. The chapter on the anatomy of the lumbosacral spine is well written and illustrated. The chapter on the pharmacology and toxicity of local anaesthetics is, on the whole, well written but the authors have failed to mention the maximum doses of local anaesthetics. The North American emphasis of the book is highlighted in this section, particularly by the choice and use of drugs and drug names.

Section three covers alternative analgesia during labour and delivery. This includes topics such as TENS, acupuncture, hypnosis, systemic opioids, inhalation analgesia and other regional blocks. The use of spinal analgesia during labour is covered in great detail, including the use of combined spinal–extradural (CSE) analgesia. The clinical features and management of post-dural puncture headache (PDPH) are well covered and there appears to be no conflict in the approach to PDPH between the USA and Europe.

Section four sets out to describe the anaesthetic management of Caesarean delivery, and again, most chapters in this section offer European and American views. Anaesthesia for Caesarean section includes extradural, spinal, general and local anaesthesia. Many of these chapters are good, despite a significant amount of repetition of both extradural and spinal anaesthesia from a previous section. Included in this section is a chapter on post-Caesarean section analgesia. Unfortunately, this chapter would not be comprehensive enough for British anaesthetists. It does not mention the use of extradural diamorphine for postoperative pain relief or the use of adjuvant analgesics, such as non-steroidal anti-inflammatory drugs, which are commonly used in the UK.

Section five is a comprehensive account of the high-risk parturient and her fetus. This section covers a wide range of topics such as pregnancy-induced hypertension (PIH), cardiac and other systemic diseases, embolism, difficult intubation and aspiration of gastric contents, morbid obesity and drug addiction in the pregnant woman. Most chapters include views from continents other than North America. The chapter on cardiac diseases was readable and well done, however, I wonder if the authors did really mean to say that an ejection fraction of 0.82% is normal.

Section six deals with maternal and neonatal outcome. The chapter on maternal mortality includes the *Confidential Enquiry into Maternal Deaths in the UK* but unfortunately the latest report to be mentioned is from 1990. Hence some of the recommendations from the 1994 report are not included. Other interesting topics which have been included in this section are anaesthesia for fetal surgery, anaesthesia for *in vitro* fertilization procedures and management of the parturient after transplant surgery.

The seventh and final section covers administrative problems and controversies in obstetric anaesthetic practice. The editors have aimed to include obstetric anaesthetic services from various countries, including some developing countries. Unfortunately, the quality of these chapters was variable. Some chapters were disappointing. Finally, the chapter on standards for obstetric anaesthetic services covered only American standards and failed to mention those of any other country, such as the minimum standards recommended by the Obstetric Anaesthetists Association in the UK.

Overall, the editors of this book have been successful in covering a wide range of topics. As may be expected from the large number of contributors, there is significant repetition. It is surprising however, that on occasions, the same author repeated him/herself. The inclusion of views of several authors on one topic sometimes implied that each account gave insufficient detail for the reader to achieve full understanding. This was most obvious with the chapter on pregnancy-induced hypertension. A more comprehensive chapter by one author might have given enough detail and would have been more readable. The American emphasis was dominant throughout the book which makes it more useful for the American obstetric anaesthetist. The lists of references are good but the relative paucity of reference to publications after 1990 is disappointing for a book published in 1996. Although this is a book that I would not buy for personal use, it is well worth consideration for reference in a departmental library.

*M. C. Mushambi*

*Baillière's Clinical Anaesthesiology—Neuroprotection, vol 10, No. 3.* J. A. STAMFORD AND L. STRUNIN (editors). Published by Baillière Tindall, WB Saunders, London. Pp. 214; indexed; illustrated. Price £30.00.

The aim of this book is to update anaesthetists on the present position regarding research and development of drugs and other therapeutic means of limiting the detrimental effects of cerebral ischaemia. The editors state that the reader will benefit from reading the book as a whole rather than only selected chapters, and this is undoubtedly the case. I would recommend anyone who is interested in neuroprotection to read the whole volume The individual chapters deal with laboratory models of cerebral ischaemia, cerebral energy metabolism, neurotransmitters in cerebral ischaemia, role of calcium in ischaemic brain injury, modulation of voltage-gated sodium channels, antagonists of excitatory amino acids, free radicals, anticonvulsants and reperfusion injury, general anaesthetics as neuroprotective agents, acute management of head injury, physiological imaging of stroke and the future of neuroprotection. They provide an up-to-date description of the pathophysiological processes thought to be involved in cerebral ischaemia and a thorough evaluation of the efficacy and likely future role of pharmacological and other proposed methods for limiting neuronal damage.

The chapters are well written with useful explanatory illustrations and are pitched at the correct level for clinicians. Each chapter ends with a useful short summary of the important points and there are comprehensive lists of references at the end of each chapter. The system of referencing sometimes makes the text difficult to follow and the publishers might consider changing to the system of numbered references used by the major anaesthetic journals.

I enjoyed reading this book and learnt much from it. It achieves its aim of updating practising clinicians on the subject of neuroprotection. All anaesthetists could benefit from reading it but it will be particularly useful for intensivists, neuroanaesthetists, cardiothoracic and vascular anaesthetists. It would also make useful reading for neurosurgeons and physicians involved in the management of stroke. Therefore, it will be an important addition to the shelves of all postgraduate medical libraries.

*E. Moss*

*A Short History of Anaesthesia: The First 150 Years.* G B. RUSHMAN, N. J. H. DAVIES AND R. S. ATKINSON. Published by Butterworth Heinemann, Oxford Pp. 218 Price £16.99.

This is a lovely little book, produced primarily by the Southend team and thus owing much to the late Dr J. Alfred Lee to whose memory it is dedicated. Much of the book is based on his earlier writings in the various editions of *Synopsis of Anaesthesia*, but with the material updated and making particular reference to the many major anniversaries between 1994 and 1998.

Squeezed within its slim covers are 20 chapters and three appendices covering almost every conceivable aspect of the specialty. The first four chapters outline developments sequentially and the remaining 16 review the history of specific topics, culminating with a calendar of major events. The appendices review the organization of the specialty, early publications on anaesthesia and a bibliography of the history of anaesthesia. Each section is obviously short, but the entries are anything but superficial and the references are the really key ones. The text is as authoritative as it is comprehensive and I could find no fault with the descriptions of those aspects of the history of anaesthesia that are of particular interest to me. The volume is reminiscent of T. E. Keys' *The History of Surgical Anesthesia*, but is more up to date and more structured. This allows the reader to find material sought much more readily.

It is my firm view that anyone who is interested in anaesthesia should own a copy of this book. It would make a superb introductory text for the beginner in anaesthesia because it provides an introduction to all aspects of the specialty in a very digestible form. For everyone else it provides a definitive reference source for settling arguments and acting as a stepping stone in a search for more detailed information in the literature. I repeat, this is a lovely little book.

*J. A. W. Wildsmith*

*Pain Clinic Manual.* S. DOLIN, N. PADFIELD AND J. PATEMAN (editors). Published by Butterworth Heinemann, Oxford. Pp. 310; indexed; illustrated. Price £30.00.

The *Pain Clinic Manual* is a new book aimed at consultants, trainees, junior doctors and nurses with an interest in the management of patients with chronic pain. There are 16 contributors of whom 25% are consultant anaesthetists who specialize in pain management. Contributors from other specialties include a rheumatologist, palliative care consultant, dentist, clinical psychologist and an orthopaedic surgeon. This reflects the increasingly multidisciplinary approach to pain management and is to be commended.

The book is divided broadly into seven parts. The first part contains chapters on the pain clinic, pain patient and measurement of pain. These provide a reasonable introduction to the topic, but would benefit the trainee by containing more modern references. Part two has chapters on generalized pain patterns. The chapter on reflex sympathetic dystrophy clearly identifies the problems with diagnosis and treatment of this difficult condition, and contains 110 references (possibly a little excessive for a manual!). The third part is the largest and has chapters describing pain by anatomical location. For the most part the contributors have adhered to a similar structure for each chapter (anatomy, classification, clinical features, examination, investigation and management) which makes for easy reading. Two chapters are devoted to back pain, appropriately reflecting the large proportion of patients being referred for this difficult problem. I was concerned that one of the recommended treatments of disc prolapse was strict bedrest. It is suggested further that analgesics have little benefit, and there was no mention of physiotherapy. There are few enough clinical guidelines in pain management but they do exist for the treatment of back pain; surely we should be using them.

Part four of the book pertains to common pain problems and is generally well organized with the same structure as the previous part. Microvascular decompression (MVD) is recommended in the treatment of trigeminal neuralgia if percutaneous techniques have failed, however percutaneous procedures may reduce the success rate of MVD. Outcome studies are obviously required. In fact the general lack of outcome studies in pain management is an extremely important observation echoed by many of the contributors. The fifth part includes helpful chapters on symptom control in cancer and in human immunodeficiency disease. Information on psychological therapies and pain management programmes are addressed in the sixth part of the book and are succinct and relevant. Lastly there is a chapter on the future which suggests that the prevention of or early intervention in the treatment of chronic pain should be the way forward. The appendices on invasive procedures contain helpful technical and clinical advice.

The quality of the chapters, illustrations and references is variable, which is to be expected from a book with this number of contributors. However, my overall impression is that, despite some inconsistencies, the manual provides a reasonable guide to the problems encountered in the pain clinic and the therapeutic options available. At £30.00 the *Pain Clinic Manual* is a worthwhile investment and I would recommend it for those who need an easy guide to the management of patients as they present to the clinic.

*F. A. Campbell*

*Cardiac Surgery: Safeguards and Pitfalls in Operative Technique*, 2nd Edn. S. KHONSARI. Published by Lippincott Raven, New York. Pp. 339; indexed; illustrated. Price £149.50.

This publication is the second edition of a work first published in 1988. It is a textbook devoted to operative technique in cardiac surgery, highlighting safeguards and pitfalls. It is predominantly a single author's experience, namely Dr Siavosh Khonsari, of the University of California, Los Angeles. He acknowledges the collaboration and contribution of his colleague, Dr Colleen Sintek. The aim of the text is to provide a practical guide to surgeons in training and it also offers tips and hints that surgeons of all levels of experience will find interesting. The text is presented in a manner that is simple and easy to read.

The first three sections of the book cover general considerations of the cardiac surgical patient and surgery for acquired heart disease, including ischaemic heart disease. The techniques described are largely up to date, which is a difficult feat to achieve in a rapidly changing specialty. The topic of minimally invasive coronary artery surgery is mentioned but not described in major detail and this is understandable. No mention is made of minimally invasive techniques for valve surgery. The latter half of the book is devoted to surgery for congenital heart disease. The illustrations are excellent and potential errors in operative technique are described clearly. Interestingly, the technique of intraoperative echocardiography as a method of determining the effectiveness or otherwise of surgical treatment is not mentioned. This would have been particularly appropriate in the chapters relating to intra-cardiac repair of congenital abnormalities.

With this one criticism, I consider that this textbook is a well written guide and deserves a place in the library of any department of cardiac surgery. It is probably too expensive for surgical trainees to purchase for personal use.

*M. St J Hickey*

*Ambulatory Anaesthesia and Surgery.* P. F. White (editor). Published by WB Saunders, London. Pp. 918; indexed; illustrated. Price £90.00.

The chief editor's stated goal in writing this book was to create a comprehensive reference source which emphasized the "team concept" of health care delivery in this field. To achieve this no fewer than 119 contributors (29 of whom are non-anaesthetists) and eight consulting editors have produced a book of more than 900 pages, containing up-to-date material, referenced data and expert opinion of a very high standard

The text is divided into eight sections: five of these deal with clinical aspects commencing with "preoperative assessment and preparation" and "surgical considerations and concerns". "Pharmacologic principles and applications" deals with basic pharmacokinetics and individual drug groups and includes a chapter on techniques of local anaesthesia. "Assessing recovery and outcome" deals comprehensively with everything from PONV to re-admission rates, and the final clinical section deals specifically with the management of children.

Two non-clinical sections deal with organization, management, medical economics and legal issues, covering with great thoroughness the essential requirements for, and development of, an ambulatory surgery centre. The discussion on financial matters has much of relevance to the anaesthetist working in a purchaser/provider environment, despite the American scenario.

The eighth section is an interesting "international perspective" with contributors from 17 different areas of the world describing ambulatory surgery in their country. The final pages of the book contain seven problem-orientated case studies which highlight some of the clinical dilemmas which may present to health care workers in this field

The text is long, detailed and very thoroughly referenced, using 88 pages of named references, each of which usefully details all the chapters of the book in which that reference is used. There is liberal use of photographs, figures, tables and diagrams, and overall the presentation is excellent. Almost every aspect of ambulatory anaesthesia and surgery is covered in a clear and easily understood manner. The use of American English and syntax and a setting within the American health care system presents less of a problem nowadays; the language of the modern NHS and the competitive, financial climate of trusts make a book such as this understandable and it contains much information which is relevant to hospital medicine and anaesthesia in general, out-with the day-care unit

There are minor eccentricities: quoting Sir Lancelot Spratt and using more than three pages to describe the contents of a crash cart; and irritations such as MAC means "monitored anaesthesia care", but these do nothing to diminish the value of this book. It is well prepared and edited and surprisingly readable, used as either a reference work or for casual reading. I recommend it for all departmental libraries where it will be of great interest to all those who are involved with day-case surgery and anaesthesia.

## EDITORIAL

### Effect of blood transfusion on postoperative immunocompetence

The 20th century has seen the establishment of blood transfusion as an essential part of modern medical practice, and many advances in the treatment of patients, especially in the field of surgery, would have been difficult, if not impossible, without the availability of human blood products. Along with the acceptance of blood transfusion as a beneficial form of therapy has come the realization that the collection, storage and transfer of blood from one human to another is not without risk. Side effects of transfusion range from mild allergic reactions, through bacterial and viral infection, to more serious immune-related reactions such as acute haemolysis (table 1). Febrile, non-haemolytic reactions complicate 1% of transfusions; the risks of acquiring viral hepatitis or the human immunodeficiency virus (HIV) are estimated at 1 in 5000 and 1 in 400 000, respectively (in the USA), and the risk of a fatal haemolytic reaction is approximately 1 in 600 000.[1–3] One side effect of blood transfusion that has received relatively little publicity in recent years, partly overshadowed by public and professional concern over the risk of HIV transmission, and partly because of continuing controversy over its clinical significance, is immunosuppression.

## History

Medawar was one of the first to study the immunomodulatory effect of blood transfusion in 1945 when, in a series of animal experiments, he demonstrated a commonality of antigens between blood and other tissues.[4,5] As a consequence of his findings the early transplant surgeons adopted a policy of deliberately avoiding blood transfusions, as far as was possible, in potential transplant recipients, believing that if a patient was exposed to foreign antigens from a transfusion there was a very real chance that similar antigens may later be presented to a transplant, leading to rejection. Over the next 30 yr clinicians realized instead that blood transfusion actually appeared to protect renal allografts, and in 1973 Opelz and colleagues published a large retrospective study of patients who had undergone renal transplantation, demonstrating that graft survival was increased by up to 20% in those who had received a transfusion before transplantation.[6] The greatest benefit was seen in patients receiving five or more transfusions, and it appeared that transfusion of blood was responsible for down-regulation of the recipient's immune system in some way. Over the next 10 yr the attitude of transplant surgeons changed from one of deliberate avoidance to that of deliberate transfusion. Units developed procedures for both donor-specific and random donor transfusion, resulting in an increase in the 1-yr graft survival rate from 40% to 60%.[7]

## Mechanisms of immunomodulation

Despite the progress in our understanding of immunology there is, as yet, no clear explanation as to how transfusion of allogenic blood causes suppression of the recipient's immune function. Some authors believe that transfusion itself is not responsible for a so-called "transfusion effect", rather that it is a surrogate marker for some other event that is responsible; in the case of transplant surgery that transfusion pre-selects patients who will not become sensitized to donor antigens, and in the case of other disease processes that transfusion is a marker for severity of disease or treatment, or both, which would automatically place the subject in a worse prognostic group.[8,9] It is well recognized however that blood transfusion suppresses some aspects of the immune system, giving rise to depressed delayed hypersensitivity reactions, decreased natural killer cell activity, decreased CD4/CD8 ratios and decreased IL2 production.[10–14] There are several theories to explain these effects: *clonal deletion*—the presence of foreign MHC antigens causes deletion or inactivation of T cells with receptors for that MHC, and may occur centrally (thymic deletion) or peripherally (non-thymic deletion); *tolerance*—essentially failure to respond to antigenic stimulation, possibly by blocking of receptor sites on T cells; *active suppression*—cellular immunity may be actively down-regulated either by suppressor T cells or by sub-groups of helper T cells specific for humoral immunity.[8,15–18] It is not yet clear which of the many components of a blood transfusion is responsible for causing immunomodulation but donor leucocytes carrying foreign antigens appear the most likely, and work with leucodepleting filters for transfusions has shown amelioration of the transfusion effect.[11 12 19 20]

## Current interest

Although initial realization of the immunomodulatory effect of blood transfusion arose in the field of transplantation, the advent of powerful immunosuppressive agents (cyclosporine A in particular) and improvements in patient care (both before and after operation), patient selection, HLA matching, rejection therapy and graft perfusion/ transportation techniques, have reduced the "transfusion effect" in transplantation to negligible levels.[21] In recent years clinicians have considered if the immunosuppressive effects of transfusion may influence other aspects of patient care, and for those treating patients at or around the time of surgery (a time when the need for transfusion often arises) the concern has been whether transfusion may affect the original disease process, and whether it may contribute to patient morbidity during the recovery period. As far as postoperative immunocompetence is concerned, the three main areas of interest have been: (i) tumour recurrence rates, (ii) postoperative infection rates and (iii) clinical course of inflammatory disorders such as Crohn's disease.

## Tumour recurrence

The first report of a transfusion effect other than in transplantation was in the early 1980s when Burrows and Tartter reported their results of a retrospective review of colorectal cancer patients, demonstrating a positive association between perioperative blood transfusion and cancer recurrence.[22] Using multivariate analysis to control for covariate factors they concluded that blood transfusion was the second most important prognostic variable, after pathological staging. This first report of such a link between blood transfusion and cancer prognosis stimulated interest around the world, and to date nearly 100 studies on this subject have been published, some of which support and others which dispute the presence of such an association.[23] The majority of these studies examined colorectal cancer which is both common and often requires blood transfusion as part of its management, thus yielding large numbers for study.[24–28] The remainder have examined cancer of the breast,[29 30] lung,[31 32] kidney,[33 34] prostate,[35 36] stomach,[37 38] cervix,[39] vulva,[40] head and neck,[41 42] bone[43] and soft tissue sarcoma.[44]

The majority of this work has been retrospective in nature, and the conclusions reached by the different authors clearly demonstrate the dichotomy of international opinion. Even meta-analyses of the combined results of these studies reflect this disagreement, some showing a positive association between transfusion and tumour recurrence,[45 46] while others maintain such an association is caused by confounding variables not controlled for by the retrospective nature of the studies.[23 47]

## Postoperative infection rates

Renal allograft survival and cancer recurrence rates are both long-term markers of clinical outcome, whereas postoperative infection usually manifests within 7–14 days of surgery and would be expected to be more prevalent in patients who are immunosuppressed to a significant degree. The same workers in America who first reported on cancer recurrence rates published their results of postoperative infection rates among transfused and non-transfused patients a few years later.[48] They found an increase in infection rate from 4% to 25% which was independently associated with perioperative blood transfusion. Increased infection rates of similar magnitude have been reported for abdominal surgery,[11 49] orthopaedic surgery,[50 51] cardiac surgery[52] and trauma patients.[53 54] Overall these studies appear more supportive of the idea that perioperative blood transfusion has a deleterious effect on patient outcome, even when combined and subjected to meta-analysis.[45 55] This acceptance is still not universal, and there remains a body of opinion that this association is caused by other variables for which controls are not adequate.[56]

## Inflammatory disorders

Far less well reported is the effect that perioperative transfusion has on the clinical course of Crohn's disease, a condition which may be autoimmune in nature. Two studies have shown a 2–3-fold increase in disease recurrence in patients who were not transfused at the time of surgery, compared with those who were.[57 58] The numbers of patients in both studies were small but if the effect was real it may represent a beneficial aspect of transfusion-related immunomodulation similar to that described for transplant patients.

## Discussion

Transfusion-related immunosuppression is a real phenomenon, the mechanism of which is currently unknown. The questions facing clinicians who are responsible for transfusing patients are: is the transfusion effect clinically significant, and if so what can we do to avoid it? The debate over significance will continue until sufficiently large, controlled clinical studies provide an answer on which authorities can agree.[18 56] Transfusion of homologous blood can be avoided to a certain extent by several means in both elective and emergency surgery (table 2)[59 60] and there are several filtration systems available which can remove up to 99.9% of leucocytes from red cell products either in the blood bank or at the bedside. Until such time that more hard evidence is available

*Table 2* Methods of avoiding homologous blood transfusion

| |
|---|
| Greater use of crystalloid/colloid volume expanders |
| Meticulous haemostasis |
| Pre-deposit autologous transfusion |
| Preoperative recombinant erythropoetin |
| Iso-volumic haemodilution |
| Intraoperative blood salvage |

the issues outlined above should be used as one consideration in the decision of whether or not to transfuse. There is no doubt that judiciously timed transfusions in the perioperative period for patients who are losing significant quantities of blood are essential, but the morbidity and mortality risks of transfusion must be considered carefully in all cases.[61–64]

CLINICAL INVESTIGATIONS

# Extradural pain relief in labour: bupivacaine sparing by extradural fentanyl is dose dependent

G. LYONS, M. COLUMB, L. HAWTHORNE AND M. DRESNER

**Summary**

The minimum local analgesic concentration (MLAC) of bupivacaine in labour is defined as the effective concentration in 50% of subjects ($EC_{50}$). We have used the technique of double-blinded sequential allocation to quantify the bupivacaine sparing effect of the addition of four different doses of extradural fentanyl in 223 labouring women. There were five groups: (1) plain bupivacaine (control); (2) bupivacaine with fentanyl 1 μg $ml^{-1}$; (3) bupivacaine with fentanyl 2 μg $ml^{-1}$; (4) bupivacaine with fentanyl 3 μg $ml^{-1}$; and (5) bupivacaine with fentanyl 4 μg $ml^{-1}$. The MLAC of bupivacaine were 0.069% w/v, 0.057% w/v, 0.048% w/v, 0.031% w/v and 0.015% w/v, respectively. We observed a reduction in MLAC of 18%, 31% ($P$=0.03%), 55% ($P$<0.0001) and 72% ($P$<0.0001) with fentanyl 1, 2, 3 and 4 μg $ml^{-1}$, respectively, demonstrating a significant negative linear trend ($P$<0.0001) with increasing fentanyl dose. The incidence of pruritus was increased significantly with fentanyl 4 μg $ml^{-1}$ ($P$=0.0015). Because of this, fentanyl 3 μg $ml^{-1}$ may be the optimal dose when the aim is bupivacaine sparing extradural analgesia during labour. (*Br. J. Anaesth.* 1997; **78**: 493–497).

**Key words**

Analgesia, obstetric. Analgesic techniques, extradural. Anaesthetics local, bupivacaine. Analgesics opioid, fentanyl.

The addition of extradural fentanyl to extradural bupivacaine in labouring women has been claimed to hasten onset of analgesia, increase its duration, diminish perineal discomfort[1] and reduce the amount of bupivacaine required to achieve comfort without motor block.[2 3] It improves maternal satisfaction[4] and may reduce the need for instrumental delivery.[5] Addition of fentanyl did not improve the quality of labour analgesia when given with plain bupivacaine at concentrations in excess of 0.2% w/v,[6] but permitted weaker concentrations to become effective in clinical practice.[7] This has prompted the use of dilute solutions of extradural bupivacaine in combination with opioids to achieve satisfactory analgesia but with a reduction in unwanted local anaesthetic effects such as motor block.[5] In this respect, extradural administration of sufentanil has been shown to reduce the requirement for bupivacaine in clinical practice by 20%,[8] but the relationship between varying doses of opioid and bupivacaine has never been adequately quantified.

Studies comparing efficacies of extradural analgesics have been hindered by ignorance of the relative potencies of the agents concerned, whether alone or in combination. Anaesthetic potencies of volatile agents have been described in terms of minimal anaesthetic concentration (MAC), and the same concept can be applied to extradural analgesics. An equianalgesic dose or concentration, or visual analogue pain score (VAPS) for both single agents and drug combinations would provide an extradural alternative to MAC. One such equianalgesic measure is the minimum local analgesic concentration (MLAC) of bupivacaine in labour.[9] This has provided a model which allows estimation of potency, and permits the bupivacaine sparing effect of successive doses of extradural opioid to be quantified. The aim of this study was to use this clinical model to access the ability of successive doses of extradural fentanyl to reduce the requirement for extradural bupivacaine, given to women in labour, using doses of fentanyl in the clinical range.

## Patients and methods

Our hospital Ethics Committee approved this study. After obtaining informed consent, we studied 223 women, ASA I or II, requesting extradural pain relief in the first stage of labour. We excluded those women in whom cervical dilatation exceeded 6 cm, and those who had received opioid or sedative drugs. Use of transcutaneous electrical nerve stimulator and Entonox before extradural request were not regarded as exclusion criteria.

Extradural blocks were sited in a standard manner. An i.v. infusion of 0.9% saline was started via a forearm cannula. The extradural space was found using a 17-gauge Tuohy needle, either at L2–3 or L3–4, in the sitting position. Loss of resistance to saline was used to identify the extradural space, limiting the injection to 2 ml in order to minimize dilution of local anaesthetic. For the purpose of the study, the test dose was omitted.

---

G. LYONS, FRCA, L. HAWTHORNE, FRCA, M. DRESNER, FRCA, St James's University Hospital, Beckett St, Leeds LS9 7TF
M. COLUMB, FRCA, Withington Hospital, Nell Lane, Manchester M20 2LR. Accepted for publication: January 21, 1997

The first administration of bupivacaine or bupivacaine–fentanyl was a freshly prepared syringe containing 20 ml of test solution given over 5 min. This was bupivacaine diluted with 0.9% saline to achieve the desired concentration at room temperature, with or without fentanyl, according to the groups below, which were studied in sequence.

### CONCENTRATIONS AND DOSES OF FENTANYL STUDIED

Forty women were included in each of five groups: (1) bupivacaine control, starting concentration was 0.1% w/v; (2) bupivacaine and fentanyl 1 $\mu$g ml$^{-1}$, starting concentration was 0.07% w/v; (3) bupivacaine and fentanyl 2 $\mu$g ml$^{-1}$, starting concentration was 0.06% w/v; (4) bupivacaine and fentanyl 3 $\mu$g ml$^{-1}$, starting concentration was 0.05% w/v; (5) bupivacaine and fentanyl 4 $\mu$g ml$^{-1}$, starting concentration was 0.04% w/v.

Doses of fentanyl were constant for each group. The first woman in each group received an arbitrarily chosen concentration of bupivacaine based on estimations of MLAC from preceding studies. Thereafter, the concentration of the test solution in each individual syringe was determined by the response of the previous patient to the higher or lower concentration in her test syringe, according to up and down sequential allocation. Routine maternal cardiovascular and fetal monitoring were performed.

### ASSESSMENT

The efficacy of the first dose was assessed using a 100-mm VAPS where 0 represented "no pain" and 100, "worst pain ever", at 0, 15 and 30 min after injection of the test solution (first dose). Three outcomes were possible.

#### *Effective*

This required that VAPS decreased to 10 mm or less at the height of contraction, within 15–60 min. This indicated the end of the study and directed a decrease of 0.01% w/v bupivacaine for the next woman.

#### *Ineffective*

This followed failure of the VAPS to reach 10 mm within 30 min of the test solution. If at 30 min the woman claimed satisfactory analgesia despite not reaching the VAPS target of 10 mm, the study period was extended to a maximum of 60 min. At 30 min, after failing to reach the VAPS target, rescue analgesia consisting of 0.25% w/v bupivacaine 12 ml was offered. After this, a reduction in VAPS to 10 mm or less indicated the end of the study and directed a 0.01% w/v bupivacaine increase for the next woman.

#### *Repeat*

Failure to achieve a VAPS of 10 mm, in the presence of pain outside T10–L1 distribution, or when the rescue bolus failed to achieve a VAPS of 10 mm or less, indicating either a source of pain other than the first stage of labour, or a technical failure of the extradural, directed that the same concentration be repeated for the next woman.

For all women, age, weight, height, gestation, parity, cervical dilatation, use of oxytocin and pruritus were recorded.

### STATISTICAL ANALYSIS

Patient and obstetric data were collected and are presented as mean (SD) and median (interquartile range) as appropriate. The median effective concentration was estimated from the up–down sequences using the formula of Dixon and Massey which enabled MLAC with 95% confidence interval to be derived.[10] The data were also subjected to Wilcoxon and Litchfield probit regression analysis as a back-up sensitivity test. Additional analyses included: Komolgorov–Smirnov test for Gaussian distribution, ANOVA, Bonferroni correction for multiple comparisons, post-test for linear trend, Kruskal–Wallis test, Fisher exact test and mid-$P$ value estimation for discrete data.[11 12] All analyses were carried out on two personal computers (Dell Dimension XPS P100c and Zenith Z-Star EX 486DX 50) using the following software: Microsoft Excel 5.0a for Windows, Statistical Package for the Social Sciences (SPSS) 6.1 for Windows, GraphPad Instat 2.05a for DOS and Pharmacologic Calculation System (PCS) 4.2 for DOS. Statistical significance was defined for an overall $\alpha$ error at the 0.05 level. All $P$ values were two-sided with multiple comparison corrections applied as appropriate.

Sample size estimations were based on the results of the first MLAC studies which showed the MLAC of bupivacaine to be 0.065% (SD 0.037%).[9] A conservative $\alpha$ error of 0.01 was applied to allow for multiple comparisons. Power was given at 0.9, with the minimum significant difference a 50% reduction in the MLAC of bupivacaine by fentanyl. It was then estimated that a minimum of 39 women would be required per group.

## Results

There were no significant differences in patient or obstetric characteristics between the groups (table 1).

There were significant dose-dependent reductions in the MLAC of bupivacaine with fentanyl 2 $\mu$g ml$^{-1}$ ($P=0.03$), 3 $\mu$g ml$^{-1}$ ($P<0.0001$) and 4 $\mu$g ml$^{-1}$ ($P<0.0001$) compared with the bupivacaine control (table 2). This was demonstrated also by a significant negative linear trend for the MLAC of bupivacaine ($P<0.0001$) with increasing fentanyl doses.

Sequences of effective and ineffective analgesia are shown in figure 1.

There were significant reductions in the repeat rates with fentanyl 2 $\mu$g ml$^{-1}$ ($P=0.038$), 3 $\mu$g ml$^{-1}$ ($P=0.038$) and 4 $\mu$g ml$^{-1}$ ($P=0.01$) compared with bupivacaine control (table 3).

Pruritis was increased significantly by fentanyl

## Discussion

We have shown that the addition of extradural fentanyl to extradural bupivacaine in labour produced a dose-dependent reduction in the requirements for bupivacaine. Significant reductions were obtained with fentanyl 2, 3 and 4 $\mu$g ml$^{-1}$ (40 $\mu$g, 60 $\mu$g and 80 $\mu$g). The latter dose, however, caused a marked incidence of pruritus (23%). Although fentanyl 4 $\mu$g ml$^{-1}$ proved to be the most effective in terms of bupivacaine sparing, the cost in side effects may well make a dose of 3 $\mu$g ml$^{-1}$ the choice for clinical practice. Doses in excess of 4 $\mu$g ml$^{-1}$ were not studied because of the increasing incidence of pruritus. Eight patients in the 4-$\mu$g ml$^{-1}$ group received test solutions that did not contain local anaesthetic. Further reductions in MLAC could be achieved only by an increase in opioid only recipients, up to a maximum number of study patients. Clearly, at a dose somewhere in excess of 4 $\mu$g ml$^{-1}$, clinically important reductions in bupivacaine concentration would become hard to achieve. Comfort in labour has been achieved with fentanyl alone.[2]

### TEST DOSE

In common with others, we did not use a test dose.[7] Because of its sensitivity and specificity in the detection of i.v. injection,[13] we used 2% w/v lignocaine 1 mg kg$^{-1}$ as an extradural test dose. Our earlier study[9] suggested that this dose can have a therapeutic effect. The MLAC of lignocaine was 0.37% w/v, which corresponds to a median effective dose of 74 mg. It is clear that a test dose of this magnitude might interact with the efficacy of subsequently administered extradural analgesics. We have found in our own clinical practice that

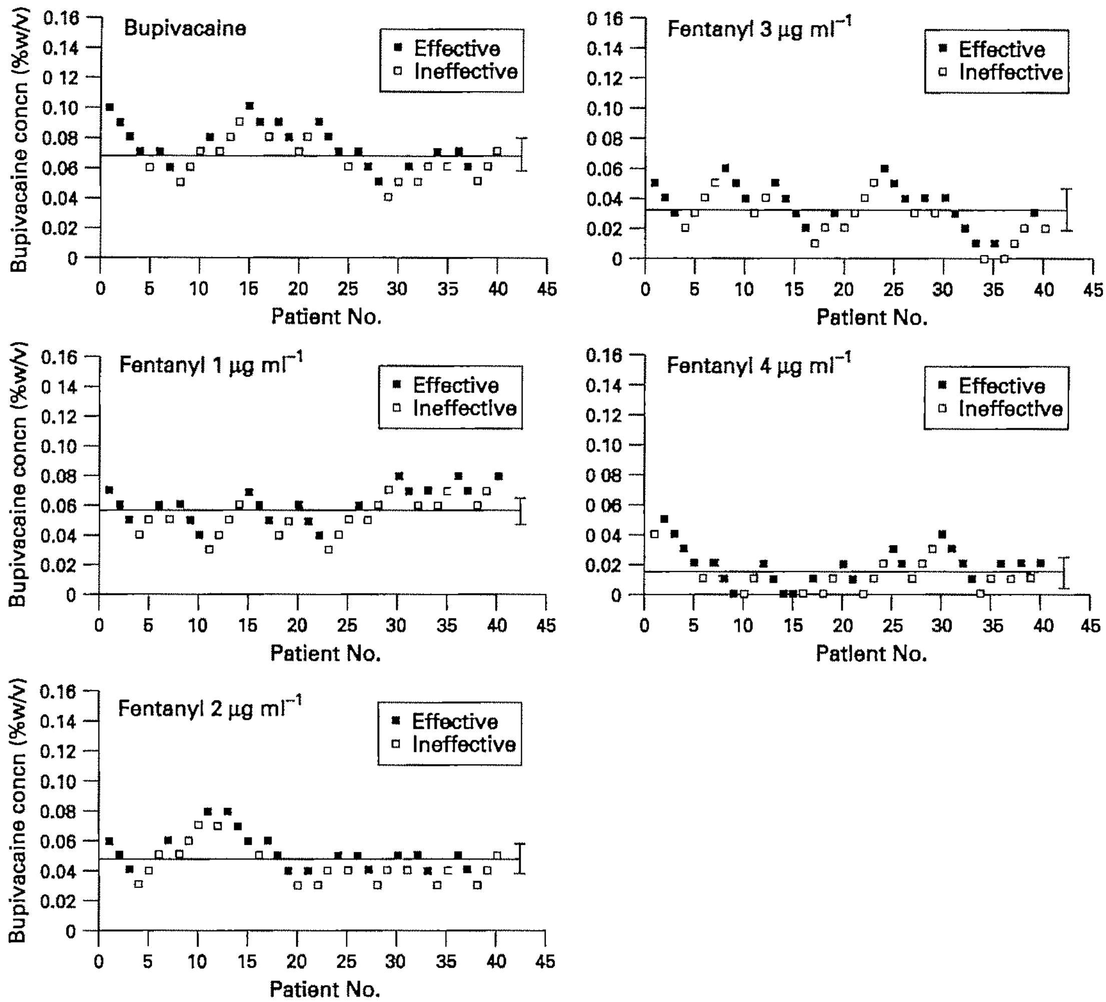

*Figure 1* EC$_{50}$ of bupivacaine, fentanyl 1, 2, 3 and 4 µg ml$^{-1}$, as determined by the technique of up-down sequential allocation. Error bars represent 95% confidence interval. Testing interval was 0.01% w/v.

2% w/v extradural lignocaine 1 mg kg$^{-1}$ achieves satisfactory comfort in approximately 40% of women, and its inclusion would have interfered with interpretation.

## TARGET VAPS

Determining the EC$_{50}$ for an analgesic implies that analgesia fails in 50% of the sample. Brownridge has shown that in labour, a VAPS of 30 mm or less corresponds to comfort.[14] Sensitive to the request for pain relief, we chose as our target a VAPS of 10 mm. While making the required degree of analgesia more exacting, it ensured that approximately 30% of the "ineffective" solutions produced VAPS below Brownridge's comfort line.

## RESCUE

After an "ineffective" solution it was important that pain was abolished rapidly. There was also a concern that failure to meet the target VAPS might be caused by a technical problem of the extradural or by pain from a source outside the normal distribution of first stage pain, and not a genuine therapeutic failure. To achieve comfort rapidly, and simultaneously demonstrate that the extradural was capable of analgesia with bupivacaine alone, the rescue was devised in a volume, and at a concentration that we considered would meet these aims unequivocally. Milligan and colleagues showed that 0.25% w/v bupivacaine 12 ml produced analgesia to at least the T10 dermatome in 80 women.[15]

## REPEATS

When the test solution produced analgesia in a first stage distribution, but the VAPS exceeded 10 mm because of persistent, generally perineal, discomfort, we chose to repeat that concentration. While there was a subjective element to this assessment, it was necessary to ensure that only the concentration of local anaesthetic decided therapeutic efficacy. The degree of subjectivity in making this assessment influenced directly the number of repeats. Any bias this introduced operated equally for all groups as the investigators were blinded to the concentrations used throughout the studies. The addition of fentanyl 2 µg ml$^{-1}$ or greater reduced significantly the number of instances when therapeutic failure was in doubt. Failure of rescue indicated the need to resite the extradural, and necessitated a repeat of the test solution in the subsequent woman.

STATISTICAL ANALYSIS

The formula of Dixon and Massey was used to derive MLAC and 95% confidence interval from the results of sequential allocation.[9] Regression techniques have been used by other workers to analyse similar up–down data, so we applied probit regression as a back-up sensitivity test.[16] We believe that the former test is more appropriate even though the latter is generally less conservative with the data. Regression analysis is usually applied to randomly rather than sequentially allocated data. This is in keeping with theoretical arguments that the observations in up–down allocation are not completely independent and that the possibility of heteroscadesis is not necessarily examined. In stating this, however, we do not wish to be critical of other workers as the two analyses return reasonable approximations to each other.

The power of these studies (1.0, range 0.36–1.0 for the observed results) suggests overestimation of the required sample size to find significance for a 50% reduction in the MLAC of bupivacaine by fentanyl. This was probably caused by an initial overestimation of the SD.

We believe that comparisons of arbitrarily chosen analgesic recipes are an inappropriate method of dose finding in labour and that there is a need to create a benchmark for extradural analgesics. A suggestion that this can be done with equimolar solutions[17] has some value, but clinical practice requires a benchmark for analgesia. Estimation of equianalgesia (MLAC) allows the contribution of components of a drug cocktail to be quantified, and doses adjusted for best effect. When comparative studies are performed with equianalgesic combinations, best solutions are identified, not in terms of analgesia, but in terms of undesirable effects

In summary, we have shown that extradural fentanyl reduced the requirement for extradural bupivacaine during the first stage of labour in a dose-dependent manner. We have also shown that by combining it with bupivacaine, the number of blocks deemed to be deficient in spread (repeats) was reduced significantly. By inference, increasing doses of extradural fentanyl should permit greater motor sparing, but this requires further study. Fentanyl 4 μg ml$^{-1}$, while producing the greatest depression of MLAC (78%), produced a significant amount of pruritus, and for this reason fentanyl 3 μg ml$^{-1}$ may represent the optimum dose.

# Combined spinal–extradural anaesthesia for preterm and term Caesarean section: is there a difference in local anaesthetic requirements?

K. S. JAMES, E. MCGRADY AND A. PATRICK

## Summary

In a non-blinded observational study, we have tested the null hypothesis that there is no difference in local anaesthetic requirements for subarachnoid anaesthesia between women presenting for Caesarean section at term or preterm (38–42 and 28–35 weeks' gestation, respectively). Using a combined spinal–extradural technique, 2.25 ml of 0.5% hyperbaric bupivacaine was given, in the sitting position, to 50 women presenting for Caesarean section. In 21 of 25 preterm women, adequate sensory block for surgery did not develop ($P<0.001$) and they required supplementary extradural local anaesthetic (median 8 ml of 2% lignocaine with 1:200 000 adrenaline (interquartile range 4–12 ml)); preterm women not requiring extradural supplementation were at the upper end of the gestational range. There was a strong linear correlation between increasing gestation and block height in the preterm group (Spearman rank correlation coefficient=0.74; 95% confidence intervals 0.49, 0.88). All women in the term group developed adequate anaesthesia with the subarachnoid dose alone. Onset of anaesthesia was slower in the preterm group (median 15 *vs* 5 min) with a lower incidence of hypotension ($P=0.0005$). (*Br. J. Anaesth.* 1997; **78**: 498–501).

**Key words**
Anaesthesia, obstetric. Anaesthetic techniques, extradural. Anaesthetic techniques, subarachnoid. Anaesthetics local, bupivacaine.

In the UK, the Caesarean section rate is rising with a disproportionate increase in the number of preterm Caesarean sections.[1 2] In 1995 just over 11% of Caesarean sections were performed on mothers at less than 36 weeks' gestation[1 2] and improving obstetric and neonatal management allows a better prognosis for these babies. Babies have better Apgar and neurobehavioural scores when mothers have a regional rather than a general anaesthetic[3–5] and as preterm babies are already compromised, it seems sensible to use an anaesthetic technique which avoids giving depressant drugs to both mother and fetus. Despite this, a large proportion (39%)[6] of mothers receive a general anaesthetic for Caesarean delivery which may be related to the fact that standard textbooks give little guidance on the management of regional anaesthesia for preterm Caesarean section.

Pregnant women at term require less subarachnoid local anaesthetic than non-pregnant women to achieve a given sensory block.[7–9] While it has been suggested that preterm women require the same local anaesthetic dose as those at term,[10 11] our own clinical observations suggested that preterm women needed larger doses to achieve adequate sensory block for surgery.

The aim of this study was to assess if a standard subarachnoid dose of local anaesthetic produced similar sensory block levels in women at term and preterm (38–42 and 28–35 weeks' gestation, respectively), presenting for Caesarean section, and to test the null hypothesis that there is no difference in local anaesthetic requirements between these groups.

## Patients and methods

After obtaining hospital Ethics Committee approval, we studied 50 women who gave written informed consent. We used 25 women as controls, presenting for elective Caesarean section at term, and 25 women required delivery by Caesarean section between 28 and 35 weeks' gestation.

With the mother in a sitting position, a combined spinal–extradural kit was used with a standard 16-gauge Tuohy needle and a 117-mm long 26-gauge pencil-point spinal needle, designed to pass through the lumen of the extradural needle after location of the extradural space, and which can extend up to 12 mm beyond the end of the extradural needle (Portex Ltd). After a preload of 15 ml $kg^{-1}$ of crystalloid solution the extradural space was located with the 16-gauge Tuohy needle using loss of resistance to saline and the 26-gauge pencil-point needle passed through the lumen of the Tuohy needle into the subarachnoid space. When CSF was seen in the hub of the needle, 2.25 ml of 0.5% hyperbaric bupivacaine was injected over 30 s without barbotage. The spinal

Correspondence to K. S. J.

needle was then withdrawn, an extradural catheter inserted and secured, and the mother immediately placed supine with 20° left lateral tilt.

Sensory block height was measured 3 min after subarachnoid injection and then at 2-min intervals until it had stopped rising. As we were performing repeated measurements, we chose to measure block height with loss of cold sensation. A block to T4 was considered necessary before allowing surgery to start. Assessment of the block to pinprick was made at this time and anaesthetic (feels nothing) and analgesic (aware of pinprick but not sharp) block heights were recorded. If the subarachnoid block stopped increasing (three consecutive block measurements without change) before it reached T4, supplementary extradural local anaesthetic was added. We injected 2 ml of 2% lignocaine with adrenaline 1:200 000 for each dermatome level between the maximum height of the subarachnoid block and T4.

Block height after subarachnoid injection alone, supplementary extradural local anaesthetic requirements, maximum block height, time taken to reach T4 and the incidence of hypotension (a decrease in systolic pressure to <70% of pre-spinal level) were recorded. Statistical analysis was performed with Minitab for Windows version 9.2 using the chi-square test, Mann–Whitney *U* test and Spearman rank correlation as appropriate.

Hospital clinical audit showed that 99% of women presenting for elective Caesarean section at term achieved a block to T4 with 2.25 ml of 0.5% hyperbaric bupivacaine. We can assume that if only 70% of preterm women achieved a suitable block this would be clinically important (i.e. 30% failure rate). As the outcome is either success or failure the statistical test is the difference in two binomial proportions. With a significance level of $P<0.01$ and a power of 0.99, the sample size required for each group (term and preterm) was 21. We studied 25 patients in each group in case data were lost.

## Results

With the exception of gestational age, both groups were similar (table 1). The numbers of preterm women at each week of gestational age are shown in table 2.

There was a significant difference between the term and preterm groups in maximum block height after subarachnoid injection ($P<0.001$). All women at term developed an anaesthetic block to T4, but 84% of preterm women failed to achieve a T4 block (table 3).

There was a strong linear correlation between increasing gestational age and block height produced with subarachnoid local anaesthetic alone (Spearman rank correlation=0.74: 95% confidence intervals 0.49, 0.88) (fig. 1).

The four preterm women who developed a block to T4 were at the upper end of the preterm gestational age limit; three at 35 weeks' and one at 34

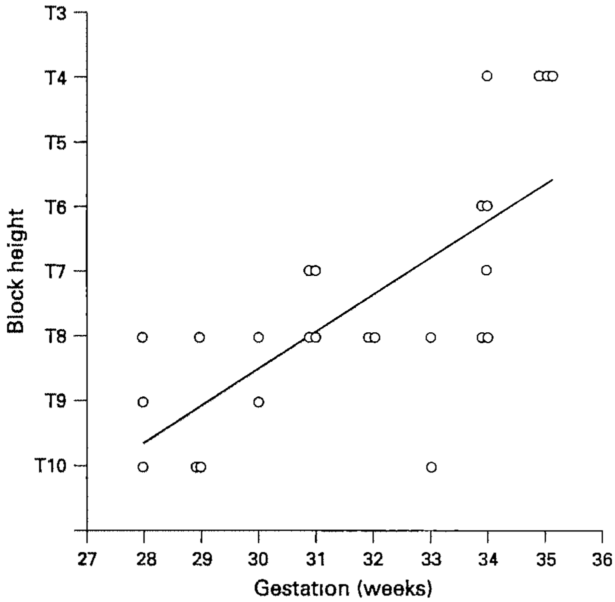

*Figure 1* Correlation between maximum sensory block height achieved with subarachnoid anaesthesia alone and gestational age.

*Table 3* A: Sensory block to T4 with subarachnoid local anaesthetic alone (*P* value. chi square=36.207, df 1, $p<0.001$), B: time to T4 and maximum sensory block height after addition of extradural local anaesthetic if required (median (interquartile range)) (*P* values: Mann–Whitney *U* test); C: hypotension (*P* value: chi square=12.00, df=1, $P=0.0005$)

weeks' gestation. Five other woman at 34 weeks' gestation did not develop a block to T4 and required supplementary extradural local anaesthetic. All other preterm women were less than 34 weeks' gestation and all required supplementary extradural local anaesthetic.

The median time to achieve a block to T4 was 5 min in the term group and 15 min in the preterm group ($P<0.001$) (table 3). The maximum time taken for any patient to develop a T4 block in the preterm group was 22 min.

Maximum block heights were higher in the term group receiving subarachnoid local anaesthetic alone compared with the preterm group after addition of supplementary extradural local anaesthetic (medians T3 and T4, respectively) ($P=0.0008$) (table 3).

There was significantly less hypotension in the preterm group, with only four women with a 30% decrease in arterial pressure ($P=0.0005$) (table 3).

## Discussion

Our results confirmed that, using the technique described, a standard subarachnoid dose of local anaesthetic, appropriate for women at term, failed to reliably provide adequate anaesthesia for preterm women requiring Caesarean section. All women with a gestational age less than 34 weeks required supplementary extradural local anaesthetic to achieve sensory block to T4.

Why do preterm women require more local anaesthetic? It is known that women at term require less local anaesthetic than non-pregnant women, and this seems to be related to physiological and hormonal changes in pregnancy. It is known that in late pregnancy the gravid uterus compresses the inferior vena cave, impairing venous return from the legs and pelvis,[8] and it has been assumed that as the collateral circulation includes the extradural veins, resultant distension of extradural veins effectively reduces the volume of both the extradural and subarachnoid spaces, altering the distribution of drugs injected into the CSF.[8 9] This has been confirmed by Hirabayashi and co-workers, who have demonstrated, using magnetic resonance images, that the extradural venous plexus is engorged in the supine parturient compared with the same women before pregnancy.[12] The engorged extradural veins also displace the dura, thereby decreasing the volume of the subarachnoid space. In addition, increased CSF prostaglandin concentrations in pregnancy increase the sensitivity of nerves to local anaesthetics,[13 14] and this may also contribute to a reduction in local anaesthetic requirements.

Preterm women, in late second or early third trimesters, with a smaller uterus than those at term, presumably have less inferior vena caval compression, less collateral flow through the extradural venous plexus and therefore larger extradural and subarachnoid volumes. In addition, the effect of prostaglandins on nerves may be related not only to increased prostaglandin concentrations but also to the duration of exposure to the increased concentration, with preterm women having had shorter exposure times.[15]

We induced subarachnoid anaesthesia with women in the sitting position and chose a 2.25 ml (11.25 mg) dose of hyperbaric bupivacaine as 2 ml (10 mg) has been shown to be inadequate in 37.5% of term women,[16] and a single space combined spinal–extradural technique was used so that women could receive supplementary extradural local anaesthetic if required. We found that this technique provided a gradual onset of anaesthesia with a reliable block height (no patient developed an inappropriately high block) and minimal hypotension, which should be beneficial to the compromised preterm fetus. Although using extradural 2% lignocaine and adrenaline 1:200,000 minimized the onset time of extradural block,[17] as expected it took significantly longer to achieve a T4 block in the preterm group. The difference in median times to T4 was 10 min, unlikely to be clinically important in most cases. In keeping with a slower onset of sensory block, the incidence of hypotension was significantly lower in the preterm group ($P=0.0005$).

We attempted to identify factors which might reliably predict sensory block height after subarachnoid injection and found a strong linear correlation between increasing gestational age and higher blocks (Spearman rank correlation=0.74: 95% CI 0.49, 0.88). Given why we believe preterm women need more local anaesthetic, it would seem logical that there would be some association between uterine size and local anaesthetic requirements. We assessed uterine size by measuring fundal height taken from the symphysis pubis to the fundus and found a correlation between gestational age and fundal height (Spearmann rank correlation=0.55, 95% CI 0.20, 0.77) and between fundal height and block achieved with subarachnoid local anaesthetic (Spearman rank correlation=0.85, 95% CI 0.68, 0.93) (fig. 2). Although uterine size may be more important than gestational age in predicting dose requirements it is difficult to measure accurately.

In summary, we have shown that subarachnoid

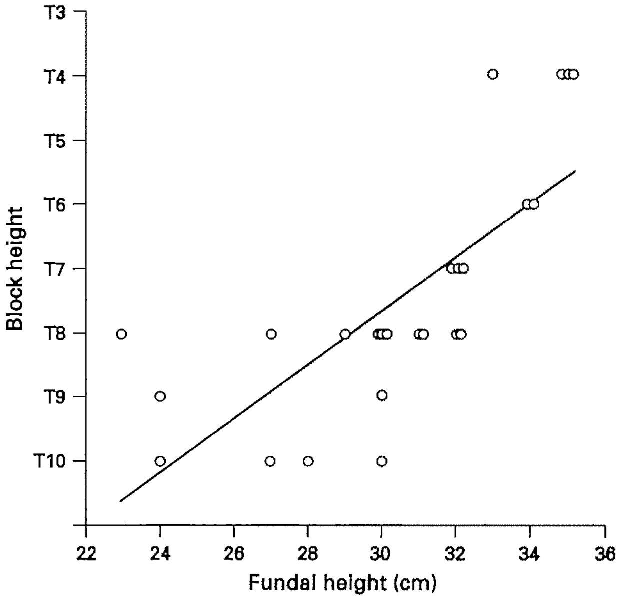

*Figure 2* Correlation between maximum sensory block height achieved with subarachnoid anaesthesia alone and fundal height.

injection of 2.25 ml of hyperbaric bupivacaine, with women in a sitting position, failed to provide adequate anaesthesia for Caesarean section in 84% of preterm women and we can reject the null hypothesis that subarachnoid local anaesthetic requirements in these two groups are the same. Preterm women required more local anaesthetic and there was a strong correlation between increasing gestation and higher block for a given dose of local anaesthetic. However, it is difficult to predict accurately the dose for an individual preterm patient and the combined spinal–extradural technique should be used when time allows, as this produces reliable and stable anaesthesia with little hypotension. If urgent Caesarean section is required and a single dose subarachnoid anaesthetic is planned, a larger dose of local anaesthetic should be used.

# Effect of lignocaine and pH on propofol-induced pain

M. ERIKSSON, S. ENGLESSON, F. NIKLASSON AND P. HARTVIG

## Summary

Propofol has the disadvantage of pain on injection. A higher partition of propofol in the aqueous phase of the preparation causes a higher incidence of pain on injection while addition of 1% lignocaine to propofol reduces pain. The low concentration of this local anaesthetic and the rapid pain relief observed indicates that mechanisms other than local anaesthesia are involved, that is change in pH. We performed a clinical study to investigate the influence of lignocaine and pH on pain during injection of 1% Diprivan. Ten parts of 1% Diprivan were mixed with one part of saline, 1% lignocaine or hydrochloric acid to achieve the same pH as that after addition of lignocaine. Diprivan 1% mixed with 1% lignocaine and with hydrochloric acid gave mean pain ratings (1–10) of 0.32 (SD 0.75) (*n*=25) and 0.88 (1.30) (*n*=24), respectively. These ratings were significantly lower than ratings after injection of a saline–Diprivan mixture (2.18 (2.06), *n*=22). The pH of the 1% Diprivan formulation decreased after mixing with 1% lignocaine. The concentration of propofol in the aqueous phase was lower when 1% Diprivan was mixed with 1% lignocaine (0.376 g $\text{litre}^{-1}$) or HCl (0.392 g $\text{litre}^{-1}$) compared with 1% Diprivan and saline (0.476 g $\text{litre}^{-1}$) mixed in the same proportion. Thus pH changes may modify propofol-induced pain on injection by a mechanism different from the effect of the local anaesthetic on the vascular endothelium. Our findings may explain why lignocaine mixed with propofol causes less pain than injection of lignocaine followed by propofol. (*Br. J. Anaesth.* 1997; **78**: 502–506).

**Key words**
Formulations, propofol. Formulations, pH. Pain, injection. Anaesthetics i.v., propofol. Anaesthetics local, lignocaine.

Propofol (Diprivan; 2,6-diisopropyl phenol) causes pain on i.v. administration.[1] Initially it was formulated in Cremophor EL which may increase the risk of anaphylactic reactions and as a consequence propofol was formulated as an aqueous emulsion in soybean oil.[2 3] Dissolving diazepam and etomidate in soybean oil (Intralipid) almost abolished the pain associated with their injection[4 5] but the same is not true for propofol although pain is known to be related to the aqueous concentration of propofol in the emulsion.[6 7] Pain after injection of propofol is thought to be caused by direct stimulation of venous nociceptive receptors or free nerve endings, the nerve impulse being transmitted by thinly myelinated A delta fibres.[8] If a local anaesthetic affects these nerve cells it must penetrate the cell membrane in its uncharged form and is then converted to its ionized form which anaesthetizes intracellular receptors.

Pain on injection induced by propofol has been found to be reduced by a preceding injection of lignocaine.[2] A direct effect of local anaesthetics on vascular smooth muscle has been suggested.[9] Comparisons between the efficacy of lignocaine injected before propofol and of mixtures of lignocaine and propofol injected simultaneously have shown that the latter causes less pain on injection.[3 10] Knowledge of the mechanism by which a small amount of lignocaine counteracts pain caused by subsequent injection of propofol is valuable. Small quantities of local anaesthetic can reduce such pain at the injection site, but also the pain observed at more proximal sites. This suggests an effect of lignocaine on propofol-induced pain on injection separate from its local anaesthetic action.

It is not clear how such low concentrations of lignocaine mixed with propofol (e.g. 1:10) and thereby diluted to a 0.1% solution almost instantaneously prevents propofol-induced pain on injection. Alternative explanations for the efficacy of lignocaine on injection pain caused by propofol include: lignocaine hydrochloride is a weak free base–cation solution which, when exposed to lipids, liberates protons as the free base dissolves in the lipids, thereby decreasing the pH of the mixture; the lower pH produced after mixing lignocaine with Diprivan reduces the concentration of propofol anions as propofol is a weak acid with a $pK_a$ of 11. The net effect would be an increased amount of propofol which migrates into the lipid phase. Such an effect would result in reduced pain on injection.[7 11]

In order to determine if the change in pH achieved by adding lignocaine to the Diprivan solution or the local anaesthetic effect of lignocaine is the main mechanism for reduction of pain on injection, we observed the responses of solutions in which the pH

change was created by lignocaine or by addition of hydrochloric acid. Diprivan 1% mixed with lignocaine, hydrochloric acid or saline, all three with the same degree of dilution, were prepared and tested in patients. Chemical analysis was also performed whereby pH titrations were made with 1% Diprivan mixed with increasing amounts of lignocaine or hydrochloric acid. These titrations were also made with 10% and 20% Intralipid solutions, the former corresponding to the emulsion used in 1% Diprivan.

## Patients and methods

### PAIN DETERMINATION

After obtaining approval from the local Ethics Committee of the University of Uppsala and the Swedish Medical Products Agency, we studied 44 patients (18 males), ASA I or II, undergoing elective ENT surgery. All patients gave informed consent to participate in this study. Mean age was 43 (range 18–72) yr. Patients were requested to name which of two propofol injections, one in each hand, at its maximum caused most discomfort and in addition to grade the pain, where "0"=no pain, "1"=hardly recognizable and "10"=extreme pain. Premedication was with ketobemidon (Ketogan Novum; an analogue to morphine) 2.5–5 mg and atropine 0.5 mg or glycopyrronium (Robinul) 0.2 mg injected i.m. 30 min before induction of anaesthesia. A 20-gauge i.v. cannula was inserted in a dorsal vein of each hand. Coded ampoules containing 2 ml of either sterile 1% lignocaine, sterile hydrochloric acid 0.064 mol $litre^{-1}$ or saline were prepared in advance. No efforts were made to stratify the material. Diprivan 1% (10 ml) at room temperature was mixed with 1 ml of the contents of a randomly chosen ampoule. All mixtures were prepared immediately before injection and all injections were made in a double-blind manner. Two millilitres of the mixtures were injected simultaneously in each cannula over a period of 25–30 s.

### DRUGS AND EQUIPMENT

We used propofol (1% Diprivan; Zeneca AB, Sweden), lignocaine (1% Xylocain; Astra AB, Sweden) and a soybean oil emulsion (Intralipid; Kabi Pharmacia AB, Sweden), similar to the solvent in which propofol is emulsified. pH values of each compound and the mixtures were determined with a pH meter (PHM 92, Radiometer, Copenhagen, Denmark) calibrated at pH values of 4.00 and 7.00. All experimental procedures were performed at least in duplicate.

Analysis of propofol and lignocaine concentrations was performed by liquid chromatography of the aqueous phases obtained by ultracentrifuging the Diprivan preparations. These analyses were performed by Dr Björn Norlander, Department of Clinical Pharmacology, University of Linköping.

Diprivan 1% was mixed randomly (10+1) with 1% lignocaine, hydrochloric acid 0.0064 mol $litre^{-1}$ or saline and administered into surgical patients in a double-blind, randomized manner.

The following chemical experiments and titrations were performed with Diprivan and Intralipid mixed with either lignocaine, hydrochloric acid or saline: pH was measured in 1% Diprivan and in the commercially available 1% and 4% solutions of lignocaine. pH was also measured in the mixture (10:1) of 1% Diprivan and 1% lignocaine. A titration was also made with increasing amounts of lignocaine (10:2, 10:4) and the pH of each mixture measured. A new titration with 4% lignocaine was also made (10:0.25, 10:0.5, 10:1, 10:2, 10:4) which added the same amount of lignocaine to 1% Diprivan.

### STATISTICAL ANALYSIS

Analysis of variance was used to test the hypothesis of no difference between treatment groups. If this hypothesis was rejected at the 5% level using the *F* test, least-square means were calculated and compared between each pair of treatment groups. The magnitude of the differences was explored by use of 95% confidence limits. Results are expressed as mean (SD).

## Results

### *IN VIVO* EXPERIMENTS

Pain rating after administration of 10 parts of 1% propofol mixed with one part of either 1% lignocaine, hydrochloric acid 0.0064 mol $litre^{-1}$ or saline, respectively, was determined verbally. The highest pain rating was observed in the group of patients that received 1% propofol mixed with saline (table 1).

The discomfort caused by injection of 1% propofol mixed with saline was significantly higher than

that caused by injection of 1% propofol mixed with either 1% lignocaine or hydrochloric acid 0.0064 mol litre$^{-1}$ in the same ratio. The difference in pain rating between 1% propofol mixed with 1% lignocaine and 1% propofol mixed with hydrochloric acid 0.0064 mol litre$^{-1}$ was not significant (table 2).

There was a difference in pain rating between the patients' two hands even when identical mixtures were injected. The mean difference was 1.13 (SD 1.06) ($n$=15). This "subject reporting error" may be considered as a methodological error of the pain rating.

### *IN VITRO* EXPERIMENTS

The pH of the 1% Diprivan formulation varied between 7.97 and 8.02, while the pH of 1% lignocaine was 6.75. The resulting pH after mixing 1% Diprivan with 1% lignocaine in a ratio 10 to 1 was 6.32. An even lower pH was measured after increasing the volume of 1% lignocaine or increasing the lignocaine concentration (table 3). It is noticeable that the pH of this mixture was lower than that of 1% Diprivan or 1% lignocaine. A similar pH was obtained by mixing Diprivan with hydrochloric acid 0.0064 mol litre$^{-1}$ in the same ratio.

A typical pH curve is shown in figure 1.

*Table 5* Concentration (g litre$^{-1}$) and deviation (%) of propofol in the aqueous phase of a commercial preparation (1% Diprivan) *per se* and after addition of saline, 1% lignocaine or hydrochloric acid (HCl) 0.0064 mol litre$^{-1}$ in a ratio of 10+1

| Mixture | Concentration | Deviation |
|---|---|---|
| 1% Diprivan | 0.495 | |
| 1% Diprivan+saline | 0.476 | — |
| | *vs* | *vs* |
| 1% Diprivan+1% lignocaine | 0.376 | −21% |
| 1% Diprivan+HCl 0.0064 mol litre$^{-1}$ | 0.392 | −18% |

The soybean oil concentration of 1% Diprivan is 10%. Increasing volumes of 4% lignocaine added to both 10% and 20% soybean oil mixtures resulted in further lowering of the pH (table 4).

Diprivan 10 mg ml$^{-1}$ mixed with 1% lignocaine (10+1) separated into two immiscible layers within a few days, whereas 1% Diprivan mixed with saline or hydrochloric acid 0.0064 mol litre$^{-1}$, respectively, appeared stable on prolonged storage at room temperature. No macroscopic changes in these solutions were seen when stored in the dark for several months.

The concentration of propofol in the aqueous phase of 1% Diprivan was 0.495 g litre$^{-1}$. The aqueous concentration of propofol decreased in proportion when 1% Diprivan was mixed, and thus diluted, with saline. Diprivan 1% mixed with 1% lignocaine or hydrochloric acid 0.0064 mol litre$^{-1}$ (10+1) was also analysed regarding the concentration of propofol in the aqueous phase of these mixtures. The concentrations of propofol in the aqueous phase decreased markedly when either 1% lignocaine or hydrochloric acid 0.0064 mol litre$^{-1}$ was added (table 5).

The concentration of lignocaine in this phase was 1.015 g litre$^{-1}$. This concentration did not differ from that expected.

## Discussion

After addition of 1% lignocaine or hydrochloric acid 0.0064 mol litre$^{-1}$, 1% Diprivan caused less pain on injection compared with addition of saline. Addition of 1% lignocaine to 1% Diprivan caused propofol to migrate from the aqueous phase of the 1% Diprivan emulsion into its lipid phase. This migration was accompanied by a change in pH. There was an inverse relationship between pH and amount of lignocaine added, not only to 1% Diprivan but also to the soybean emulsion (Intralipid) in which propofol is formulated. An increased proportion of propofol in the lipid phase caused less pain on injection.[6,7] The lesser discomfort caused by injection of a mixture of lignocaine and propofol, compared with for example saline and propofol, may be explained only partly by the local anaesthetic action of lignocaine. This is suggested by the fact that lignocaine mixed and administered together with propofol is more effective in preventing pain on injection than pretreatment with lignocaine.[3 10] Propofol- induced pain on injection occurs quite slowly[10] giving lignocaine an opportunity to induce local anaesthesia. However, the amount of lignocaine and the injection technique are not the only important factors, but also local factors such as the contact between lignocaine and the vascular endothelium. Prolonging the effect of i.v. lignocaine on the vascular endothelium by proximal venous stasis eliminates the pain caused by subsequent injection of propofol.[12 13]

We observed a decreased incidence of pain on injection caused by 1% Diprivan when mixed with lignocaine. It is known[14] that the pH of the 1% Diprivan solution decreases when lignocaine is added and that this decrease is greater for larger doses of lignocaine. The question we tried to elucidate in this study was whether or not analgesia is obtained by local anaesthesia from lignocaine or indirectly from the decrease in pH. Therefore, a similar change in pH was created by adding hydrochloric acid to the 1% Diprivan. The results showed that the addition of hydrochloric acid to 1% Diprivan produced pain relief and that local anaesthesia by lignocaine was the less important factor for pain relief. There are three reasons for this: (1) pain prevention is instantaneous and the onset of anaesthesia from a local anaesthetic usually takes some time; (2) the concentration of lignocaine was less than 0.1%, too low for rapid onset of anaesthesia; and (3) the pH of the solution was so low that the proportion of lipophilic and diffusible free base of the lignocaine was insignificant in the water phase of the solution from which the local anaesthetic would be expected to come.

Comparisons between groups of patients are difficult to interpret as highly variable pain ratings were reported after injection of the same test solution in the same patient. This might be because of variations in the technique and rate of injection (although these were standardized as far as possible), in the area of vascular endothelium exposed to the solution and intra-individual differences in pain perception of blood vessels. This variation contributed to difficulties in isolating the effect of pH alone. Theoretically, a lower pH gives a higher fraction of propofol in an uncharged form with higher partition to the micelles of the soybean emulsion. Efforts have been made to change the emulsion formulation. Addition of blood to propofol[15] increases the amount of propofol in the emulsion phase. Also, an increased amount of fat decreases the aqueous partition of propofol by nearly 60%.[11] This deviation is more pronounced than that observed for 1% Diprivan and 1% lignocaine, and 1% Diprivan and hydrochloric acid 0.0064 mol litre$^{-1}$ (−21% and −18%, respectively) compared with 1% Diprivan and saline. However, the main difference between our findings and theirs is that we detected a higher concentration of propofol in the aqueous phase. It is reasonable to assume that this difference was caused by different methodological procedures (equilibrium dialysis[11] *vs* ultracentrifugation (this study), respectively). Also, micelles may be soluble in both the aqueous and lipid phases of the emulsion. Because of this difference, the main focus should be on the physicochemical events and changes, not absolute levels.

The pH of the solution resulting from mixing 1% Diprivan with 1% lignocaine was even lower than the pH of the two ingredients by themselves. This finding might be because of changes in the surface area structure of the micelles. The decrease in pH *per se* does not cause the emulsion to stratify, as the mixture between 1% propofol and HCl 0.0064 mol litre$^{-1}$ is macroscopically stable for several months. The same is not true when 1% lignocaine is mixed with 1% propofol.[16]

The mechanism by which propofol induces pain on injection is still not known. The release of kininogens may contribute to its origin[10 17] while vascular prostaglandin receptors do not seem to be important.[18] Local anaesthetics may bind to the vascular endothelium and binding of the local anaesthetic directly to propofol might also reduce its analgesic effects. Such an effect might explain the observed reduction of propofol-induced pain on injection by metoclopramide,[19] a structural analogue of procainamide but almost entirely lacking in local anaesthetic activity. However, a pH-lowering effect of the metoclopramide solution might also now be suggested as the principal mechanism for the reported pain relieving effect.

# Central nervous and cardiovascular effects of i.v. infusions of ropivacaine, bupivacaine and placebo in volunteers†

K. KNUDSEN, M. BECKMAN SUURKÜLA, S. BLOMBERG, J. SJÖVALL AND N. EDVARDSSON

## Summary

We have compared the incidence of CNS symptoms and changes in echocardiography and electrophysiology during i.v. infusions of ropivacaine, bupivacaine and placebo. Acute tolerance of i.v. infusion of 10 mg $min^{-1}$ was studied in a crossover, randomized, double-blind study in 12 volunteers previously acquainted with the CNS effects of lignocaine. The maximum tolerated dose for CNS symptoms was higher after ropivacaine in nine of 12 subjects and higher after bupivacaine in three subjects. The 95% confidence limits for the difference in mean dose between ropivacaine and bupivacaine were −30 and 7 mg. The maximum tolerated unbound arterial plasma concentration was twice as high after ropivacaine ($P<0.001$). Muscular twitching occurred more frequently after bupivacaine ($P<0.05$). The time to disappearance of all symptoms was shorter after ropivacaine ($P<0.05$). A threshold for CNS toxicity was apparent at a mean free plasma concentration of approximately 0.6 mg $litre^{-1}$ for ropivacaine and 0.3 mg $litre^{-1}$ for bupivacaine. Bupivacaine increased QRS width during sinus rhythm compared with placebo ($P<0.001$) and ropivacaine ($P<0.01$). Bupivacaine reduced both left ventricular systolic and diastolic function compared with placebo ($P<0.05$ and $P<0.01$, respectively), while ropivacaine reduced only systolic function ($P<0.01$). (*Br. J. Anaesth.* 1997; **78**: 507–514).

**Key words**
Anaesthetics local, ropivacaine. Anaesthetics local, bupivacaine. Cardiovascular system, effects. Central nervous system, effects. Pharmacodynamics.

The acute and most serious adverse effects of local anaesthetics involve the cardiovascular and central nervous (CNS) systems. They are usually because of accidental intravascular or intrathecal injections, or a pronounced overdose. CNS symptoms of local anaesthetic toxicity occur before cardiovascular symptoms and signs, and include numbness of the tongue, light-headedness, visual disturbances and muscular twitching; more serious signs include convulsions, coma, respiratory arrest and cardiovascular depression. Death, probably after intravascular administration of bupivacaine and etidocaine,[1] prompted studies on the mechanism of the cardiotoxic effects of local anaesthetics and search for drugs with less cardiotoxicity.[2]

Ropivacaine is a new, long-acting local anaesthetic, related structurally to bupivacaine and mepivacaine, used as the hydrochloride of the S-enantiomer, whereas bupivacaine and mepivacaine are racemic mixtures. It is less lipid soluble than bupivacaine,[3] but its pharmacokinetic disposition is similar.[4] In preclinical studies, ropivacaine showed less CNS and cardiac toxicity than bupivacaine.[5] Studies in volunteers and patients suggest that ropivacaine is similar to bupivacaine in onset, duration and extent of sensory block, although motor block is less intense and of shorter duration.[6–9]

The objective of this study was to determine if ropivacaine is tolerated better than bupivacaine when given as an i.v. infusion to volunteers, and also to evaluate the pharmacodynamic effects in relation to arterial and venous plasma concentrations.

## Subjects and methods

We studied 12 healthy male subjects (table 1) who were assessed by physical examination, echocardiography, chest radiography and routine blood tests. No subject was receiving any medication or had a history of allergic reaction to local anaesthetics of the amide type.

The study was approved by the Ethics Committee of the Sahlgrenska University Hospital and written informed consent was obtained.

### DRUG ADMINISTRATION

Drugs were administered according to a randomized (Latin squares), double-blind, crossover design to compare ropivacaine and bupivacaine with placebo; four subjects were allocated randomly to each of the

†Presented in part at the XIV Annual European Society of Regional Anaesthesia Congress, Prague, Czech Republic, September 3–16, 1995.

three treatments. Before the study, all subjects were familiarized with the initial CNS effects of i.v. lignocaine (Xylocard 100 mg 5 $ml^{-1}$, Astra Hässle AB, Mölndal, Sweden, batch RB531) at a rate of 100 mg $min^{-1}$. Ten subjects received the full 200-mg dose and two subjects 180 mg. CNS symptoms appeared in all subjects and disappeared within 5–20 min. Lignocaine infusion was given between 3 and 111 (mean 34) days before the first blind infusion.

Before each blind infusion, subjects fasted for at least 6 h. Two i.v. cannulae were inserted into antecubital veins, one in each arm, and an arterial cannula in the left radial artery. Allen's test was performed before arterial cannulation to ensure normal collateral circulation through the ulnar artery. On six occasions, subcutaneous injection of 1% lignocaine 1 ml was given 30 min to 2 h before administration of the study drug to anaesthetize the skin before insertion of the arterial cannula. Subcutaneous injection of 1% mepivacaine 1 ml was given once because of painful insertion of the catheter. A transoesophageal atrial stimulation (TAS) electrode (Medtronic 6992) was introduced, after which the subjects rested for 30 min.

Each subject received ropivacaine 5 mg $ml^{-1}$ (Astra Pain Control, Sweden, batch 471-24-1), bupivacaine 5 mg $ml^{-1}$ (Astra Pain Control, Sweden, batch 417-46-1) and placebo (sodium chloride 9 mg $ml^{-1}$; Astra Pain Control, Sweden, batch 400-62-1) by i.v. infusion (Imed 960 volumetric infusion pump, Imed Scandinavia, Sweden). Different arms were used for drug infusion and blood sampling. The infusion rate was 2 ml $min^{-1}$, corresponding to 10 mg $min^{-1}$ of active drug.

Subjects were observed continuously by the attendant anaesthetist and were asked frequently open questions to describe any symptoms during and after infusion until complete disappearance of all symptoms. The infusion was discontinued at definite signs and symptoms of CNS effects or at the request of the subject. Otherwise, a maximum dose of 250 mg was given. In practice, no infusion was discontinued at the request of the subject. The subjects were recumbent during and for up to 2 h after infusion. The mean number of days between blind infusions was 50 (range 3–179).

### ASSESSMENT OF CARDIOVASCULAR EFFECTS

A 12-lead ECG was recorded every 2–3 min from 5 min before and until 5 min after the infusion was stopped, and then 10 min after the end and 2 h after the start of the infusion. PQ interval, QRS width and QT intervals from the Q wave to the end of the T wave, QTe, and to the top of the T wave, QTt, were recorded and QTc calculated. The electrocardiographic variables were measured as the mean of five consecutive values. The same variables were recorded during TAS, 5 min before and immediately after the infusion had been stopped and the echocardiogram had been recorded. Stimulation was applied at 100 or 120 beat $min^{-1}$, or both, in order to achieve comparable heart rates.

Doppler echocardiography was performed using an Acuson 128 XP computed sonograph equipped with a 2.5-MHz transducer. All subjects were investigated in a slightly left lateral supine position. Echocardiograms were obtained 5 min before starting the infusion and then repeatedly every 3 min until the end of infusion. Echocardiograms after infusion were recorded 5 and 10 min after the end of infusion and 2 h after the start. Standard parasternal and apical views were stored on videotape. Cross-sectional M-mode recordings were made on chart paper at a speed of 50 mm $s^{-1}$ for off-line measurements of left ventricular (LV) end-diastolic and end-systolic dimensions. Ejection fraction (EF), stroke volume and cardiac output were calculated according to the formulae of Teichholz and colleagues.[10] Colour Doppler was used for detection of valvular regurgitation at the mitral, aortic and tricuspid valves before and after infusion. Any regurgitation was denoted on a scale from 1 to 4, where 1 was small haemodynamically insignificant flow and 4, large acute regurgitation. Evaluation of regurgitant flows was made off-line by the echocardiographer blinded to the subjects. Pulsed-wave Doppler was used to record transmitral flow velocities from the apical four-chamber view, with the sample volume placed at the tips of the mitral leaflets. Doppler recordings were made on chart paper at a speed of 100 mm $s^{-1}$. The ratio of maximal flow velocities at atrial contraction (A) and early filling wave (E) was calculated as a variable of LV diastolic function. Transmitral flow deceleration time (MV dec), reflecting early diastolic properties of the left ventricle, was also measured. All echocardiographic and Doppler values represent the average of three consecutive cardiac cycles.

Intra-arterial systolic and diastolic arterial pressures were recorded before starting the infusion and every 1 min until the end, and also every 5 min until 30 min after the end of infusion.

Subjects were monitored for 4 h after infusion. A follow-up comprising physical examination and clinical laboratory tests was performed 2–3 weeks later.

### BLOOD SAMPLING AND DRUG ASSAY

Samples of 5 ml of arterial and venous blood were obtained (Venoject) immediately before drug administration, and 2, 5, 10, 15, 20, 25, 30, 35 and 45 min, and 1 and 2 h after starting the infusions.

Plasma was separated within 1 h of collection, frozen immediately and stored at −20 °C. Total concentrations of ropivacaine and bupivacaine base were measured by gas chromatography.[11] The limit of quantification of the method was 0.008 mg $litre^{-1}$, interassay precision approximately 5% and recovery close to 100%. Free concentrations of ropivacaine and bupivacaine were assayed by coupled-column liquid chromatography after ultrafiltration of the plasma samples. Ropivacaine and bupivacaine were detected by UV at 210 nm and the limit of measurement was 0.003–0.008 mg $litre^{-1}$.[12] Intra-assay precision was 3–9 % for the two drugs determined from spiked plasma samples.

### STATISTICAL METHODS

A sample size of 12 subjects was determined to have a power of approximately 90% and a type I error of 5% based on a mean difference in tolerated i.v. dose of 26 mg and with an SD of 25 mg.[13]

The main analyses of treatment differences were based on a parametric model assuming Gaussian distributed errors. A general linear (ANOVA) model comprising effects for subject, period, direct treatment and (residual) error was used to describe the variation in dependent variables. Tests for equality between all three treatments were performed using $F$ tests and pairwise treatment comparisons with the two-sided $t$ test using $\alpha \leq 0.05$ in all tests. Data from all three treatment groups were used to estimate residual (error) variance. In addition to the tests, 95% confidence intervals for pairwise treatment differences were calculated.

Concentration data were collected only for bupivacaine and ropivacaine treatment periods.

The association between dose or drug concentration and physiological effects and tolerance was evaluated. Symptoms were grouped in different categories before breaking the code. Total and unbound drug plasma concentrations were estimated in arterial and venous blood. The probability of experiencing CNS symptoms with increasing concentrations was estimated in plots of arterial free plasma concentration at the start of symptoms compared with the cumulative number of subjects with symptoms. The actual plasma concentration at the onset of symptoms was interpolated linearly between two adjacent points if no value was available at the time of measurement. The analysis was based on symptoms grouped in the following categories: hearing and/or visual disturbances, perioral numbness, tingling, paraesthesia and/or paralysis, muscular twitching and/or muscular rigidity, and dysarthria. The accumulated frequencies of various symptoms were classified into categories.

Data are reported as mean (SD).

## Results

### MAXIMUM TOLERATED DOSES

Nine of 12 subjects tolerated a higher and three a lower dose of ropivacaine compared with bupivacaine. All subjects tolerated the full placebo dose (table 1). The mean dose of ropivacaine (115 mg) was higher than that of bupivacaine (103 mg) (ns). The estimated 95% confidence limits for the difference in means between ropivacaine and bupivacaine were −30 and 7 mg.

### MAXIMUM TOLERATED PLASMA CONCENTRATIONS

Unbound arterial plasma concentrations at the end of infusion, that is at the maximum tolerated dose, were consistently higher in all subjects after ropivacaine (table 1), and individual concentration ratios of ropivacaine to bupivacaine ranged from 1.2 to 4.7. Mean arterial unbound plasma concentrations were approximately twice as high after ropivacaine than after bupivacaine ($P<0.001$). Total and unbound venous and total arterial plasma concentrations were similar after both drugs (table 2). Total and unbound arterial plasma concentrations were consistently higher than corresponding venous concentrations with both drugs during and up to 20 min after the end of infusion.

### CNS SYMPTOMS

Symptoms of CNS toxicity occurred in all subjects during administration of active drug. The first symptom appeared after 2–8 min of infusion of both drugs. The most common symptoms were visual and hearing disturbances, dysarthria, tingling, perioral numbness, dizziness, paraesthesia, light-headedness, muscular twitching and muscular rigidity (fig. 1). More subjects reported muscular twitching after bupivacaine ($P<0.05$). After placebo, one subject

reported tremor in the chin and another paraesthesia in the arms and numbness in the thumb, but the infusion was not interrupted.

Objective signs, for example muscular rigidity, muscular twitching and dysarthria, were frequent end-points for stopping the infusion, and one or more of these signs or other symptoms were observed in 10 subjects after ropivacaine and in all subjects after bupivacaine. The time from the end of infusion to disappearance of all symptoms was shorter after ropivacaine (13 (11) min) than after bupivacaine (20 (16) min) ($P<0.05$).

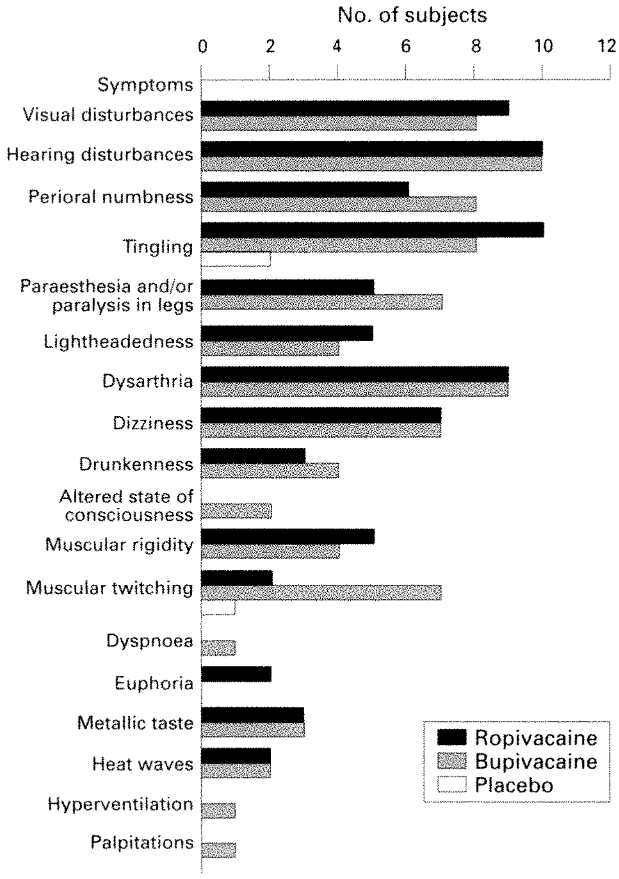

*Figure 1* Number of subjects with symptoms, grouped in different categories, during and after i.v. infusion of ropivacaine and bupivacaine 10 mg $\text{min}^{-1}$ and placebo (saline). Crossover study in 12 volunteers.

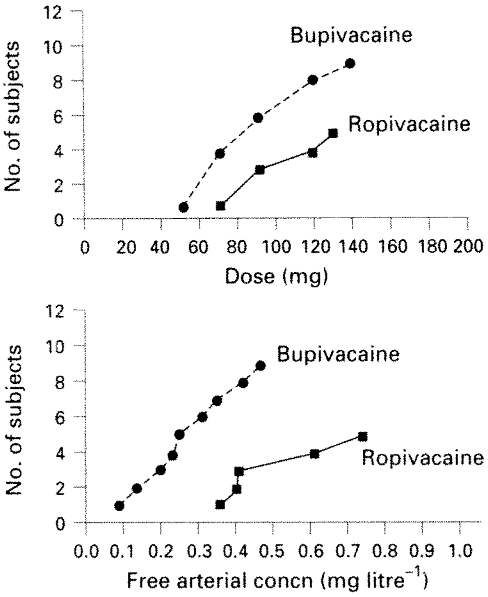

*Figure 2* Cumulative number of subjects with muscular twitching or rigidity, or both, against dose (top) or unbound arterial plasma concentration (bottom) at onset of i.v. infusion of ropivacaine and bupivacaine 10 mg $\text{min}^{-1}$. Crossover study in 12 volunteers.

Ropivacaine dose–response and concentration–response curves for CNS symptoms were shifted consistently to the right compared with those of bupivacaine. This shift meant that symptoms of CNS toxicity appeared earlier and in more subjects at a certain dose or plasma concentration when bupivacaine was given. This difference between drugs was more pronounced for muscular twitching and muscular rigidity (fig. 2) than for dysarthria.

### ARTERIAL PRESSURE AND HEART RATE

Both drugs increased systolic arterial pressure compared with placebo (table 3) ($P<0.001$). The mean increase in systolic pressure was 7% after ropivacaine and 9% after bupivacaine.

Bupivacaine was associated with an increase in diastolic arterial pressure in all subjects ($P<0.001$ *vs* placebo), whereas diastolic pressure increased in 10 of 12 subjects given ropivacaine. The mean increase was larger (26%) after bupivacaine than that after ropivacaine (13%) ($P<0.05$ *vs* placebo). There was a 12% increase in heart rate after both ropivacaine and bupivacaine ($P<0.01$ and $P<0.001$ *vs* placebo).

### ELECTROCARDIOGRAPHY

Bupivacaine increased QRS width in nine of 12 subjects at the end of infusion (fig. 3). The increase (6%) was significant relative to that for ropivacaine (three of 9 subjects (2.4%)) ($P<0.05$) and placebo (−0.4%) ($P<0.05$). During TAS at 120 beat $\text{min}^{-1}$, both ropivacaine (8.5%) and bupivacaine (9%) showed a significant increase in QRS width compared with placebo ($P<0.05$). PQ interval and QTc did not change.

QTt decreased in eight of nine subjects given ropivacaine and in 10 of 12 subjects given bupivacaine, with mean decreases of −5.7% and −5.3%. QTe decreased in all nine subjects given ropivacaine and

*Table 3* Haemodynamic, echocardiographic and electrocardiographic changes (mean (SD))at maximum tolerated doses after i.v. infusion of ropivacaine and bupivacaine 10 mg $min^{-1}$ and placebo (saline). (saline). Crossover study in 12 volunteers.

in nine of 12 subjects after bupivacaine. Mean decreases were −3.3% and −2.5%.

On assessing the last portion of the T-wave, the (QTe-QTt) was found to have increased in four of nine subjects after ropivacaine, four of 12 subjects after bupivacaine, and in one of 12 subjects after placebo, with mean increases of 3.8% and 5.8% and a mean decrease of −3.7%, respectively. Cardiac arrhythmias were not detected.

## ECHOCARDIOGRAPHY

### *Diastolic function*

There was a shorter transmitral flow deceleration time in six of 12 subjects when bupivacaine was administered (−8.1%, $P<0.05$ *vs* placebo) compared with −5.5% after ropivacaine (fig. 4). The A/E ratio increased by a mean of 6.2% for ropivacaine and 9.3% for bupivacaine (ns).

### *Systolic function*

Left ventricular ejection fraction decreased in nine of 12 subjects after ropivacaine and in 11 of 12 subjects after bupivacaine. The mean changes in ejection fraction were −11.6% compared with −13.8% ($P<0.01$ *vs* placebo for both drugs) (fig. 4). Stroke volume decreased an average of −8.1% after ropivacaine and −12.1% after bupivacaine ($P<0.05$ *vs* placebo).

Cardiac output decreased in eight of 12 subjects given ropivacaine (−2.5%) and in five of 12 subjects given bupivacaine (−3.7%). One subject had a large

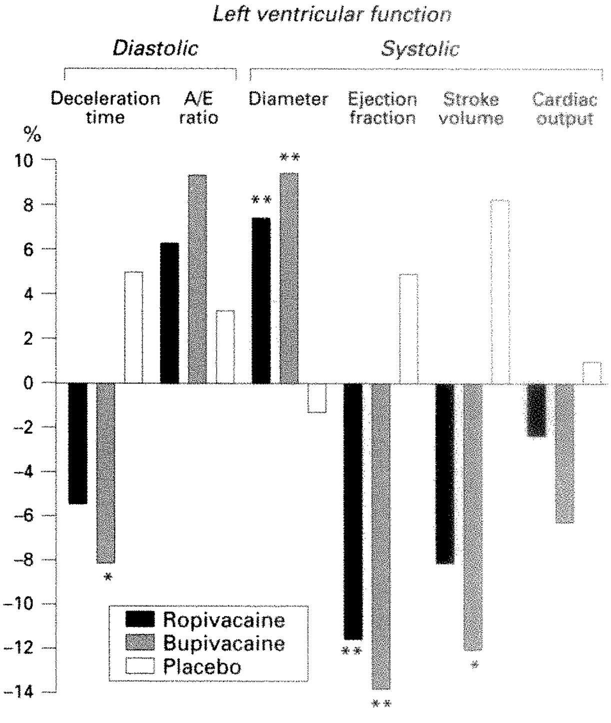

*Figure 4* Mean percentage differences in echocardiographic variables between the value at the end of infusion and baseline and at the maximum tolerated dose after i.v. infusion of ropivacaine and bupivacaine 10 mg $min^{-1}$ and placebo (saline). Crossover study in 12 volunteers.

increase in cardiac output, however, when given bupivacaine (169%), in relation to a transient increase in heart rate from 51 to 110 beat $min^{-1}$. When this subject was excluded from analysis, the mean change in the bupivacaine group was −6.4%.

No subject showed signs of pathological valvular regurgitation according to colour Doppler findings before or after infusion.

### ADVERSE EFFECTS

Transient pain and tenderness at the arterial cannulation site were reported by one subject during one blind infusion. No other adverse events occurred.

## Discussion

Tolerance of local anaesthetics has been assessed in volunteers given continuous i.v. infusions.[13–18] In general, the threshold decreases with increase in the infusion rate[16] because the maximum plasma concentration is directly proportional to the dose and inversely proportional to cardiac output and infusion time.[18] In our study, the infusion rate of 10 mg $min^{-1}$ was a rational compromise between the maximum dose allowed and the time within which the short-lasting effects could be recorded.

In all subjects receiving an active drug, the infusion was stopped because of CNS symptoms before any arrhythmia or other clinically significant changes in haemodynamic state or electrocardiography occurred. However, the results showed statistically significant changes in both cardiac conduction and contractility. These data, supported by preclinical studies showing that ropivacaine is less CNS and cardiotoxic than bupivacaine,[5] suggest that the potential of ropivacaine to produce CNS and cardiotoxicity is also less in humans. The general pattern of increasing CNS symptoms and signs and their order was similar to that reported previously with other local anaesthetics.[18]

Ropivacaine and bupivacaine produced a similar spectrum of symptoms involving the CNS, but the duration of symptoms was shorter after ropivacaine. Occasionally, early CNS symptoms made subjects temporarily unable to communicate their sensations reliably. Signs of excitatory CNS effects such as dysarthria, shivering, muscular twitching and muscular rigidity were frequent end-points for drug administration. Thus although the decision when to discontinue the infusion of necessity contains a subjective element, the decision to stop the infusion in this study could in all but two cases be based on objective criteria that were observed easily by the attending physician. This was probably made feasible by allowing higher maximum doses in this compared with the previous study[13] where the infusion was stopped after 150 mg regardless of symptoms. In our study nine of the 12 subjects tolerated a higher dose of ropivacaine than bupivacaine, which is comparable with corresponding results in 10 of 12 subjects in the study of Scott and colleagues.[13] The sequences of drug administration as a result of randomization in the three subjects who tolerated a higher dose of bupivacaine did not differ from sequences in subjects who tolerated a higher dose of ropivacaine. Moreover, all subjects tolerated higher unbound plasma concentrations of ropivacaine than bupivacaine, which also renders unlikely any effect caused by the sequence of drug administration.

Differences between ropivacaine and bupivacaine were identified in terms of tolerated doses, maximum tolerated free plasma concentrations and time to disappearance of symptoms. The consistent shift to the right of the ropivacaine dose–response and concentration–response curves for CNS symptoms implied that higher doses and free plasma concentrations of ropivacaine were tolerated before symptoms were elicited.

Arterial blood carries local anaesthetic to various parts of the body after systemic administration, while peripheral venous blood returning from poorly perfused sampling tissues during rapid i.v. administration is not representative of the distribution to, and concentration at, the site of action for central effects of local anaesthetics.[19 20] This is in agreement with the large arteriovenous concentration differences seen in our study. It is the free or unbound drug that is available for distribution, crossing biological membranes and binding to receptor sites where pharmacological effects are initiated. The toxic concentration, as estimated from peripheral venous free plasma concentrations after slower systemic drug input (without a marked arteriovenous concentration difference), would therefore be similar to free arterial plasma concentrations of ropivacaine and bupivacaine related to CNS symptoms in this study with a rapid drug input. A threshold for CNS toxicity was apparent at mean free arterial plasma concentrations of the order of 0.6 mg $litre^{-1}$ for ropivacaine and 0.3 mg $litre^{-1}$ for bupivacaine. A similar threshold for free venous plasma concentration has been reported to be 0.24 mg $litre^{-1}$ after a slower continuous perineural infusion of bupivacaine.[21] In a previous study,[13] CNS and cardiovascular symptoms were associated with higher peripheral venous plasma concentrations of ropivacaine than bupivacaine although, as indicated by the authors, the use of arterial samples would have been more informative.

Cardiovascular effects were more pronounced after bupivacaine than after ropivacaine at maximum tolerated doses. Although there were statistically significant changes, they were generally small and unremarkable. A similar distinction between ropivacaine and bupivacaine in the dose–response in QRS width has been reported in anaesthetized pigs.[22] The difference in systemic toxicity between ropivacaine and bupivacaine is likely to be clinically important.

In general, the cardiovascular system is more resistant to the effects of local anaesthetics than the CNS.[23] Extremely high concentrations depress spontaneous pacemaker activity in the sinus node and result in sinus bradycardia and sinus arrest. Similar depression at the AV node results in prolonged PQ/PR intervals and partial or complete AV dissociation. Local anaesthetics such as ropivacaine and bupivacaine inhibit rapid inward flow of sodium ions into cardiac cells during depolarization, thereby slowing the rate of rise of the action potential during phase 0.[24–26] Recovery from sodium channel block is faster after treatment with ropivacaine than after bupivacaine,[27] which is probably an important factor in the increased cardiotoxicity of bupivacaine. Impaired depolarization decreases cardiac contractility and increases QRS width. An increase in QRS width has been correlated with cardiotoxicity of local anaesthetics,[23] and also with quinidine and tricyclic antidepressant agents.

In this study, there was an increase in QRS width that was significantly smaller after ropivacaine than after bupivacaine; this is similar to previous findings.[13] However, our study is unique by inclusion of a placebo group, and the effect on QRS was similar after ropivacaine and placebo. The development of CNS symptoms prompted discontinuation of the infusion, which prevented an unwanted further increase in QRS width. Both QTt and the QTe intervals decreased, but not to the same degree, so that the index (QTe-QTt) increased. This change, representing a shortening of the final portion of the depolarization time, is in accord with a class IB (lignocaine-like) antiarrhythmic mode of action.

When bupivacaine was administered, both systolic and diastolic LV functions were reduced significantly compared with placebo. When using ropivacaine, only significant changes in systolic variables were noted. Ropivacaine also tended to have a shorter restoration period, although this was not tested. The significant reduction in LV ejection fraction compared with placebo was caused by an increase in LV *systolic* diameter, which might imply reduced myocardial contractility. In young individuals with borderline hypertension, it has been shown that such a small increase in systolic arterial pressure is associated with supranormal LV systolic function.[28] The increase in afterload during infusion of both drugs would not be an explanation of the observed changes in LV systolic function in this group of young, healthy individuals.

In the placebo period after the total 25 min of the investigation, there was an increase in systolic function variables, ejection fraction and stroke volume, but a decrease in heart rate with maintained cardiac output. These findings represent the normal haemodynamic reaction to the resting situation, with fluid resorption into the circulation, which increases blood volume, and increased vagal tone causing a minor decrease in heart rate.

Using echocardiography, Scott and colleagues[13] reported reduced LV systolic function after i.v. administration of ropivacaine and bupivacaine. Both drugs depressed cardiac contractility after intracoronary artery injection in anaesthetized pigs.[22]

We also evaluated diastolic function. Changes in diastolic variables are influenced by several factors, such as heart rate, sympathetic tone and loading conditions. The techniques available for measuring diastolic function are limited in different ways. Using pulsed wave Doppler, we noted a difference between ropivacaine and bupivacaine in LV filling pattern compared with placebo. Our findings indicated changes towards a more restrictive filling pattern and reduced LV compliance with bupivacaine.

There were remarkably few placebo effects on the CNS and cardiovascular system.

Ropivacaine showed a higher tolerated dose and unbound plasma concentration based on the shift in dose–response and concentration–response curves for CNS symptoms. At doses producing CNS symptoms, cardiovascular changes, such as depression of conduction and diastolic function, were less pronounced with ropivacaine compared with bupivacaine.

# Assessment of cardiovascular changes during laparoscopic hernia repair using oesophageal Doppler

E. J. HAXBY, M. R. GRAY, C. RODRIGUEZ, D. NOTT, M. SPRINGALL AND M. MYTHEN

**Summary**

We have used an oesophageal Doppler to measure aortic blood flow velocity before, during and after induction of carbon dioxide pneumoperitoneum in 10 consecutive patients, mean age 58 yr, undergoing laparoscopic hernia repair. Derived values for stroke distance, minute distance and systemic vascular resistance showed considerable interpatient variation indicating unpredictable haemodynamic responses. Five minutes after insufflation of the abdomen there was a significant increase in mean arterial pressure from 82.5 to 103.6 mm Hg ($P<0.05$) but both stroke distance and minute distance decreased significantly (mean 12.0 (SEM 1.4) cm to 9.0 (0.7) cm, $P<0.05$; and 747.5 (82) cm min$^{-1}$ to 596 (49) cm min$^{-1}$, $P<0.05$; respectively) indicating a significant decrease in cardiac output. There was a corresponding increase in the index of systemic vascular resistance from 1092 (747) to 2079 (400) ($P<0.05$) which persisted after deflation of the abdomen. Oesophageal Doppler can provide continuous online haemodynamic data with a rapid response to acute changes and may have a role in non-invasive haemodynamic monitoring during laparoscopic procedures in older patients with cardiovascular disease. (*Br. J. Anaesth.* 1997; **78**: 515–519).

**Key words**

Surgery, laparoscopy. Cardiovascular system, effects. Measurement techniques, oesophageal Doppler.

Minimally invasive laparoscopic surgery can reduce analgesic requirements and permit earlier postoperative mobilization than equivalent open procedures.[1] It has been advocated for high-risk patients with cardiac and pulmonary disease.[2] But carbon dioxide pneumoperitoneum and the Trendelenburg position produce major haemodynamic and respiratory changes.[3 4] Studies during laparoscopic cholecystectomy have shown large variations in the magnitude of changes in cardiac output, systemic vascular resistance and mean arterial pressure.[5 6]

Laparoscopic hernia repair is a recent addition to minimally invasive surgery. Many patients undergoing this type of surgery are older men with a high incidence of cardiac and respiratory impairment. Although studies in healthy gynaecological patients have shown only minor haemodynamic changes during laparoscopic procedures, this may not apply to laparoscopic hernia repair in older patients for whom little data are available. It has been suggested that invasive haemodynamic monitoring be used in patients with pre-existing cardiovascular disease undergoing laparoscopic surgery.[7]

The aim of this study was to measure haemodynamic changes during laparoscopic hernia repair using the non-invasive technique of oesophageal Doppler. Aortic blood flow velocity and the derived haemodynamic indices of stroke distance, minute distance and systemic vascular resistance were recorded before, during and after induction of pneumoperitoneum.

## Patients and methods

After obtaining Ethics Committee approval and informed consent, we studied 10 consecutive patients, ASA I–III, undergoing elective laparoscopic inguinal hernia repair under general anaesthesia. Temazepam 20 mg orally was given as premedication 2 h before operation.

On arrival in the anaesthetic room heart rate and non-invasive arterial pressure (Dinamap) were recorded. Anaesthesia was induced using alfentanil 25 μg kg$^{-1}$, thiopentone sufficient to obtund the eyelash reflex (2–4 mg kg$^{-1}$) and atracurium 0.5 mg kg$^{-1}$, and the patient's trachea was intubated. Infusions of alfentanil 25 μg kg$^{-1}$ h$^{-1}$ and atracurium 0.5 mg kg$^{-1}$ h$^{-1}$ were commenced. The lungs were ventilated with 70% nitrous oxide in oxygen. Ventilation was initially set at a tidal volume of 10–12 ml kg$^{-1}$ with ventilatory frequency adjusted to maintain an end-tidal carbon dioxide partial pressure of 5.0–5.5 kPa. Anaesthesia was maintained with isoflurane. The end-tidal concentration (Datex Capnomac Ultima, Datex, Helsinki, Sweden) was maintained constant at 0.8–1.0 MAC in each patient until the last set of study variables had been recorded. All patients received 1 litre of Hartmann's

solution in the perioperative period. At the end of the procedure neuromuscular block was antagonized with neostigmine and glycopyrronium. Postoperative analgesia was left to the discretion of the individual anaesthetist.

The same surgeon performed all operations in a standardized manner. Pneumoperitoneum was established by introduction of a Verres' needle via a 1.2-cm infra-umbilical incision. Two further ports were introduced laterally to facilitate surgery. The peritoneum was divided over the inguinal defect which was repaired with a mesh secured by staples. At the end of the procedure the pneumoperitoneum was released before removal of the ports and closure of the wounds.

Individual patient and procedure details are shown in table 1. Patient numbers referred to in the text correspond to the numbers given in table 1. Eight patients underwent unilateral hernia repair and two patients (Nos 2 and 8) underwent bilateral hernia repairs. Mean intra-abdominal pressure was maintained at less than 13 mm Hg at all times.

### CARDIOVASCULAR RECORDINGS

After tracheal intubation, an oesophageal Doppler probe (ODM 2, Deltex, Chichester, UK) was inserted through the patient's mouth and positioned approximately 35–40 cm from the teeth where well defined aortic blood flow signals could be detected. The probe was manipulated until the best signal was obtained. Five (M5) and 10 (M10) min after induction of anaesthesia, but before the first surgical stimulus, a set of baseline physiological variables were recorded: heart rate, arterial pressure, $Sp_{O_2}$, peak airway pressure, $FI_{O_2}$, ventilatory frequency, Doppler stroke distance and minute distance. These measurements were then repeated at the times shown in table 2.

On the oesophageal Doppler display, stroke distance is represented by the area under the flow velocity waveform and this represents the length a column of blood flows along the aorta with each ventricular systole. This is a linear index of left ventricular stroke volume. Minute distance is the product of stroke distance and heart rate and is a linear index of cardiac output. An index of systemic vascular resistance (SVRI) can be obtained by dividing mean arterial pressure by minute distance.[8]

*Table 2* Times for data collection during laparoscopic hernia repair

| Times | Description |
|---|---|
| M5 | 5 min after induction (baseline) |
| M10 | 10 min after induction |
| I+1 | 1 min after abdominal insufflation |
| I+3 | 3 min after abdominal insufflation |
| I+5 | 5 min after abdominal insufflation |
| T | Immediately after Trendelenburg positioning |
| T+5 | 5 min after Trendelenburg positioning |
| T+30 | 30 min after Trendelenburg positioning |
| EDSX | End of surgery |
| PDEF | After abdominal deflation |

Data were analysed using the Statview SE+ Graphics (Concepts Inc. Berkeley, CA, USA) statistical system. Statistical analysis was performed with a two-way analysis of variance for repeated measures and $P<0.05$ was considered significant. Results are expressed as mean (SEM).

## Results

Five minutes after insufflation of the abdomen (I+5) there was a statistically significant increase in mean arterial pressure (MAP) from 82.5 to 103.6 mm Hg ($P<0.05$) (fig. 1). Mean stroke distance (fig. 2) and minute distance decreased significantly at this time from 12.0 (1.4) to 9.0 (0.7) cm ($P<0.05$) and from 747.5 (82) to 596 (49) cm min$^{-1}$ ($P<0.05$), respectively, indicating a significant decrease in cardiac output. There was a corresponding increase in the index of systemic vascular resistance from 1092 (747) to 2079 (400) ($P<0.05$) (fig. 3).

Percentage changes from baseline (M5) in measured stroke distance and estimated SVRI are also shown for individual patients (figs 4, 5) and illustrate inter-patient variability. Pre-existing cardiovascular disease was present in patient Nos 1, 3, 8 and 9 (table 1).

Peak airway pressure increased significantly from 19.4 (1.2) to 25.7 (2.0) cm $H_2O$ ($P<0.05$) as did end-tidal carbon dioxide partial pressure from 4.3 (0.13) to 5.0 (0.1) kPa ($P<0.05$) (table 3). Mean arterial pressure remained significantly increased ($P<0.05$) throughout the procedure (fig. 1) as did end-tidal carbon dioxide partial pressure ($P<0.05$)

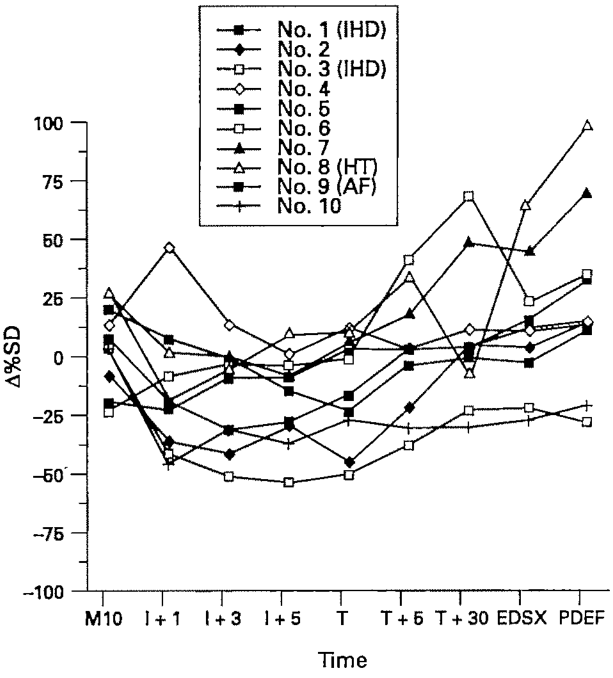

*Figure 4* Percentage change in oesophageal Doppler stroke distance (Δ%SD) from baseline (time M5) for 10 patients during laparoscopic hernia repair. Times are those shown in table 2 Patient numbers correspond to data shown in table 2. Patients with ischaemic heart disease (IHD), hypertension (HT) or atrial fibrillation (AF) are indicated.

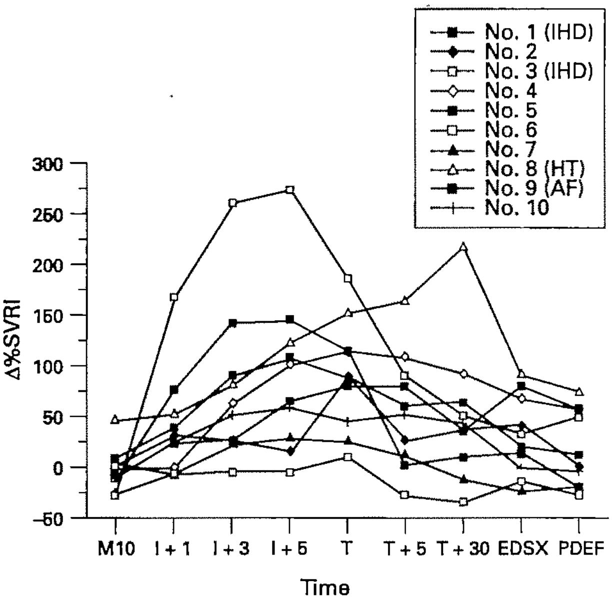

*Figure 5* Percentage change in systemic vascular resistance index (Δ%SVRI) from baseline for 10 patients during laparoscopic hernia repair. Times are those shown in table 2. Patient numbers correspond to data shown in table 2. Patients with ischaemic heart disease (IHD), hypertension (HT) or atrial fibrillation (AF) are indicated.

(table 3). During Trendelenburg positioning both minute distance and stroke distance started to increase towards pre-inflation values but SVRI remained significantly increased ($P<0.05$) compared with baseline values, even after deflation of the abdomen. There were no significant changes in heart rate and oxygen saturation throughout the procedure.

Patient No. 8 had a profound decrease in MAP on induction of anaesthesia (from 117 to 60 mm Hg) which was treated with ephedrine 6 mg. MAP increased progressively after this but did not reach pre-induction levels. Patient Nos 1 and 8 had episodes of multifocal ventricular ectopics which resolved without treatment and without new ECG

changes after operation. Patient No. 7 had an episode of hypotension 2 h after operation associated with bradycardia which was treated successfully with fluids and glycopyrronium and he also made an uneventful recovery.

## Discussion

We have used oesophageal Doppler for non-invasive haemodynamic monitoring during laparoscopic hernia repair. Despite maintaining a relatively low intra-abdominal pressure (<13 mm Hg) throughout the procedure, significant haemodynamic changes were seen. Group trends were similar to those described during pneumoperitoneum by other investigators: a relatively stable heart rate in association with an increase in MAP, decrease in indices of cardiac output and increase in the index of systemic vascular resistance during insufflation of the abdomen with carbon dioxide.[9] Inter-patient variation in cardiovascular response to insufflation of the abdomen with carbon dioxide and assumption of the Trendelenburg position was marked. This degree of variation in our small group of 10 patients suggests the need for close monitoring during laparoscopic procedures in this patient population.

Ten consecutive patients undergoing intraperitoneal laparoscopic inguinal hernia repair were selected regardless of age and medical status. Four of the group had coexistent cardiovascular disease and the changes seen in these patients were more marked than in those patients without cardiovascular disease, particularly the increase in SVRI. This subgroup with cardiovascular disease also showed greater haemodynamic variability in response to induction of anaesthesia and insufflation of the abdomen. It is not clear if this was related to underlying cardiovascular insufficiency or to cardiac medication. The anaesthetic technique was selected to provide cardiovascular stability but systemic arterial pressure decreased in all patients after induction of anaesthesia and it may have been preferable to wait longer before recording baseline variables. We made no attempt to control the fluids administered, although no patient received more than 15 ml kg$^{-1}$ of Hartmann's solution.

The oesophageal Doppler has been used extensively to monitor cardiac output and other variables in healthy subjects and critically ill patients.[8] Good agreement has been shown with thermodilution techniques.[10] In the oesophageal position, excellent signals are obtained from blood travelling through the adjacent descending aorta thereby providing continuous beat-by-beat monitoring with little artefact. The probe is easy to position and signals can be interpreted without specialist training. Waveform changes frequently preceded changes in arterial pressure or heart rate and appeared to provide earlier warning of haemodynamic deterioration.

Disadvantages of oesophageal Doppler include a small risk of injury to the pharynx and oesophagus and a requirement for anaesthesia so that prolonged postoperative monitoring may be difficult. Although probe position mostly remains stable, repositioning is occasionally required. Haemodynamic measures using this technique depend on several assumptions. It is assumed that the angle of incidence of the ultrasound beam to the direction of blood flow is the same as that of the probe face to the long axis of the instrument and that blood flow in the descending aorta remains in fixed proportion to total left ventricular output over wide ranges of flow, pressure and temperature.[7] Under resting conditions the validity of these assumptions has been supported by experimental data, but during insufflation of the abdomen, the distribution of aortic blood flow may vary and a greater percentage of cardiac output may be diverted to the head and upper body as regional afterload is altered.

Pulmonary artery catheterization has been used for haemodynamic monitoring during laparoscopic procedures.[11] This technique permits more precise calculation of left ventricular preload, afterload and oxygen delivery, which may be useful in high-risk cases. The pulmonary artery catheter may also be inserted before induction of anaesthesia and retained after operation for prolonged monitoring. These advantages must be weighed against a low but appreciable risk of morbidity which may not be appropriate for the majority of patients. Oesophageal Doppler appears to offer a safer alternative with the added benefit of continuous online display which is particularly suitable for monitoring acute haemodynamic changes.

There is no doubt that insufflation of the abdomen with carbon dioxide produces measurable effects on the cardiovascular system but the clinical significance of these is uncertain. Insufficient morbidity and mortality data are available to determine if invasive monitoring affects outcome in high-risk patients undergoing laparoscopic surgery. Extending the scope of laparoscopic techniques to older groups of patients at higher risk of cardiovascular complications requires reappraisal of haemodynamic monitoring during anaesthesia.

# Transcranial cytokine gradients in patients requiring intensive care after acute brain injury

E. G. McKeating, P. J. D. Andrews, D. F. Signorini and L. Mascia

**Summary**

After acute brain injury there may be increased intracranial production of cytokines, with activation of inflammatory cascades. We have sought to determine if a transcranial cytokine gradient was demonstrable in paired sera of 32 patients requiring intensive care after acute brain injury. The difference between concentrations of IL-1β, IL-6, IL-8 and TNFα in jugular venous and arterial serum was measured on admission, and at 24, 48 and 96 h after the primary injury. There were no differences in IL-1β, IL-8 or TNFα, but median gradients of 6.7 and 11.5 pg $ml^{-1}$ for IL-6 were demonstrated in the traumatic brain injury ($n$=22) and subarachnoid haemorrhage ($n$=10) groups, respectively (normal values in serum <4.7 pg $ml^{-1}$; $P<0.001$ both groups). This suggests that there is significant production of IL-6 by intracranial cells after acute brain injury. Therapy directed towards combatting the negative effects of IL-6 may potentially benefit patients who have sustained an acute brain injury. (*Br. J. Anaesth.* 1997; **78**: 520–523).

**Key words**
Brain, injury. Polypeptides, cytokines. Intensive care.

The cytokines are a variety of polypeptide molecules which function as mediators within the communication network of the immune system.[1] They have been implicated in the pathophysiology of many disease processes, including the systemic inflammatory response syndrome (SIRS),[2] acute respiratory distress syndrome (ARDS)[3] and multiple trauma.[4] Many of the biological effects of the cytokines are clinically evident after acute brain injury; these include neutrophilia, pyrexia and alteration of endothelial permeability,[5] which may result in cerebral oedema,[6] as a result of disruption of blood–brain barrier function.

Increased concentrations of serum tumour necrosis factor-α (TNFα),[7] interleukin-6 (IL-6)[8] and intraventricular fluid IL-6 and IL-1β[9] have been demonstrated after traumatic brain injury, and experimental work has demonstrated that glial cells are able to manufacture cytokines.[10 11] After acute brain injury it has been suggested that increased intracranial production of pro-inflammatory cytokines, with consequent induction of auto-destructive inflammatory cascades, results in secondary injury to the brain, causing altered brain metabolism and cell death.[12] With the increased use of intra-parenchymal solid state methods for monitoring intracranial pressure, access to cerebrospinal fluid for analysis is often not possible, and where it is, sampling from catheters may result in ventriculitis.[13] Insertion of a fibreoptic catheter into the jugular bulb to monitor jugular venous haemoglobin oxygen saturation is now standard practice within our intensive care unit (ICU) in acute brain injured patients, giving ready access to blood draining from the brain.[14] We investigated the hypothesis that systemic concentrations of the cytokines IL-1β, IL-6, IL-8 and TNFα are increased after acute brain injury, and that increased intracranial production of these cytokines results in a demonstrable transcranial cytokine gradient, with jugular venous concentrations higher than arterial concentrations.

## Patients and methods

After obtaining local Ethics Committee approval, we studied 32 patients who had sustained an acute brain injury (traumatic brain injury (TBI) or spontaneous subarachnoid haemorrhage (SAH)) requiring intensive care. Patient data consisting of sex, age, and Glasgow coma score (GCS) after non-surgical resuscitation were recorded on admission to the ICU (see table 1). One patient whose initial GCS was recorded as 15 was anaesthetized at the scene soon after injury because of flail chest. Computerized tomography (CT) subsequently demonstrated severe traumatic brain injury.

A dual-lumen Edslab 4-French gauge oximetry catheter (Baxter Healthcare Corporation, Irvine, CA, USA) was inserted into the jugular bulb on the dominant side of the cerebral venous drainage, as described previously.[15 16] Satisfactory positioning was ensured by lateral x-ray of the cervical spine (catheter tip seen cephalad to the upper border of the C2 vertebral body), and the correct catheter distance marking (e.g. 15 cm) showing at the valve of the sheath was written in the notes for future

*Table 1* Characteristics of patient population (median (range)). The characteristics of the subset, including only the first 20 patients, are shown in parentheses

| | TBI group ($n$=22 (12)) | SAH group ($n$=10 (8)) |
|---|---|---|
| Sex (M/F) | 18/4 (9/3) | 6/4 (4/4) |
| Age (yr) | 34 (35)<br>17–69 (17–49) | 52 (51.5)<br>21–65 (21–65) |
| GCS | 7 (7)<br>3–15 (3–15) | 7 (7)<br>5–10 (5–10) |

*Table 2* Performance characteristics of each assay. To assess intra-assay precision, three samples of known concentration were assayed 20 times on one plate. To assess inter-assay precision, three samples of known concentration were assayed in 20 separate assays

| | Intra-assay coefficient of variation (%) | | | Inter-assay coefficient of variation (%) | | |
|---|---|---|---|---|---|---|
| Sample | 1 | 2 | 3 | 1 | 2 | 3 |
| IL-1β | 3.4 | 4.4 | 2.8 | 8.4 | 4.2 | 4.1 |
| IL-6 | 4.3 | 1.7 | 2.1 | 6.3 | 3.3 | 7.2 |
| IL-8 | 3.9 | 2.4 | 3.3 | 12.2 | 9.1 | 7.3 |
| TNFα | 5.2 | 4.2 | 4.6 | 7.4 | 4.6 | 5.4 |

reference. An intra-arterial catheter was inserted (if not already *in situ*), usually in the radial artery, as is our standard practice.

Paired arterial and jugular venous blood samples were obtained at designated times after brain injury: within 12 h (median 8 h 30 min, range 2–14 h), and at 24, 48 and 96 h. Time of brain injury in the SAH group was noted as the time of sudden deterioration in GCS by 3 points or more. Patients who did not exhibit sudden neurological deterioration were not included. The diagnostic criterion for SAH was the presence of subarachnoid blood on the CT scan. Satisfactory positioning of the jugular bulb catheter was ensured before each sample was obtained by checking that the correct distance marker of the catheter was showing at the sheath valve. Samples were allowed to clot at room temperature, spun down in a centrifuge at 4000 rpm for 10 min and the supernatant removed and frozen immediately at −25 °C. Analysis of serum for IL-1β, IL-6, IL-8 and TNFα was performed by enzyme-linked immunosorbent assay (Quantikine Human Cytokine Assays, R&D Systems) according to the manufacturer's instructions. Inter- and intra-assay coefficients of variation for each assay are shown in table 2. All analyses were carried out by a single operator using the same equipment and procedures throughout. Repeat freeze–thaw cycles for serum samples were avoided by separating the serum from each patient into four tubes before freezing.

A total of 138 samples (69 pairs) were analysed in duplicate for each cytokine (with an additional 80 samples for IL-6) and results averaged to give the final concentration. Samples which gave a result higher than the highest standard supplied with the kit were diluted and the assay repeated. Sera from eight healthy volunteers were analysed as controls. Standard curves and cytokine concentrations were calculated on a personal computer interfaced to a micro-plate reader using dedicated software (Bio-Rad Laboratories). Statistical analysis was by Wilcoxon rank sum and signed rank tests using Splus for Windows 3.2.

## Results

In 119 of the 138 samples assayed for IL-1β (86%), concentrations were undetectable (<3.9 pg ml$^{-1}$). The highest concentration in the remaining 19 (14%) was 7.0 pg ml$^{-1}$. For TNFα, in 122 samples (88%) concentrations were undetectable (<15.6 pg ml$^{-1}$). The highest concentration in the remaining 16 (12%) was 31 pg ml$^{-1}$. IL-8 was detected in 72 samples (52%) (lower limit of detection 94 pg ml$^{-1}$), but only 10 (7%) showed concentrations >300 pg ml$^{-1}$. There was no difference between jugular venous and arterial concentrations of IL-1β, IL-8 or TNFα in those patients

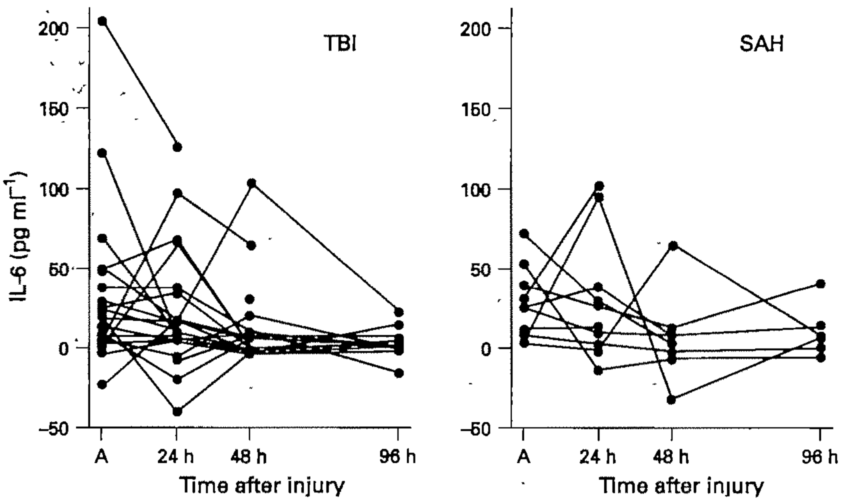

*Figure 1* Differences between jugular venous and arterial concentrations of IL-6 in traumatic brain injury (TBI, $n$=22) and spontaneous subarachnoid haemorrhage (SAH, $n$=10), over a 4-day period after injury (A=admission). Data may be incomplete because of patient death, discharge from ICU or values lying outside ELISA quantification values. For the TBI group, at each time, $n$=20, 21, 19 and 11, respectively; for the SAH group, $n$=10, 10, 8 and 6, respectively.

with detectable concentrations. Control samples all showed undetectable concentrations.

IL-6 was detected in all 218 samples. In the controls, concentrations were below detectable limits (<3.1 pg ml$^{-1}$) in four samples. The highest concentration in the remaining four control samples was 4.7 pg ml$^{-1}$. In four pairs of patient samples (3.7%), both samples showed concentrations >1500 pg ml$^{-1}$ (the upper limit of quantification) and were excluded from statistical analysis. In 82 (78.1%) of the remaining 105 pairs, jugular venous concentration was higher than arterial. In the TBI group, median jugular venous concentration was 74.8 (range 19.9–539.8) pg ml$^{-1}$), median arterial concentration was 63.5 (11.4–518.4) pg ml$^{-1}$ and the median difference was 6.7 (−40.8 to 244.4) pg ml$^{-1}$ ($P<0.001$). In the SAH group, median jugular venous concentration was 64.6 (19.1–455.4) pg ml$^{-1}$, median arterial concentration was 54.1 (12.2 to 407.4) pg ml$^{-1}$ and the median difference was 11.3 (−32 to 135.2) pg ml$^{-1}$ ($P<0.001$).

Figure 1 shows the individual patient profiles for transcranial IL-6 gradient for each group. In the TBI group, median gradients at each time point were 19.2 ($P<0.001$), 10.5 ($P=0.014$), 6.3 ($P=0.018$) and 1.6 pg ml$^{-1}$ ($P=0.147$), respectively. In the SAH group, median gradients were 26.8 ($P=0.002$), 20.1 ($P=0.027$), 5.6 ($P=0.383$) and 7.8 pg ml$^{-1}$ ($P=0.094$), respectively. Comparing the TBI and SAH groups, there was a significant difference in age between the groups ($P=0.028$), but there was no difference in GCS ($P=0.979$). There was no overall difference in IL-6 gradients across the brain between the TBI and SAH groups ($P=0.350$); there were no differences between groups at any of the four sampling times ($P=0.559$, 0.627, 0.832, 0.366, respectively).

## Discussion

We were unable to derive any useful information from measurement of either arterial or jugular venous serum concentrations of IL-1β, IL-8 or TNFα at these times after acute brain injury. It is generally believed that IL-1β and TNFα are released in the early post-injury phase,[17,18] resulting in increased synthesis of IL-6, in addition to other mediators. IL-6 may act to decrease production of IL-1β and TNFα via a negative feedback mechanism.[19] It may be that we missed an early peak of production of IL-1β and TNFα before the patients reached the ICU. The relatively high lower limit of detection for IL-8 (94 pg ml$^{-1}$) in this particular assay may have masked any significant transcranial gradient.

Results for IL-6 show increased jugular venous concentrations of this cytokine relative to arterial concentrations, particularly within 48 h of brain injury. Transcranial gradients in the TBI and SAH groups were similar, despite different aetiologies of primary injury, suggesting that the mechanisms of the inflammatory process may be similar. The median transcranial gradient on admission in each group was 5–6 times higher than the highest systemic concentration measured in the controls. This suggests significant intracranial production of IL-6. The source of this increased production is likely to be glial cells, and there is experimental evidence to suggest that both astrocytes[10] and microglial cells[11] may be involved. In addition, systemic concentrations of IL-6 were increased greatly. This may be caused solely by intracranial production, but is much more likely to be a result of release of IL-6 from extracranial sources, that is a mild SIRS. Variation in systemic concentrations of IL-6, jugular venous–arterial differences, and different patterns of concentration gradients seen over time may be related to the severity of intracranial injury, type of injury, presence of extracranial injuries or secondary insults to the brain while in the ICU.

This pattern of prolonged elevation of IL-6 is seen in SIRS and ARDS, and serum concentrations of IL-6 have been shown to be related to outcome in these conditions, both in terms of maximum concentrations detected[20] and persistence of IL-6 in serum over time.[21,22] There has been little work relating outcome in acute brain injury to IL-6 concentrations in serum. We are presently collecting outcome data for our group of patients.

A study which compared post-mortem appearances of the brains of non-survivors of traumatic brain injury in Glasgow over two periods (1968–1972 and 1981–1982) showed that the incidence of ischaemic damage had not changed, despite improved intensive care in this group of patients.[23] Analysis of our own secondary insult database of physiological variables for acute brain injured patients in the ICU revealed a significant reduction in hypotensive and hypoxic insults (i.e. periods where mean arterial pressure and arterial haemoglobin oxygen saturation decreased to below acceptable limits) to the brain over a 7-yr period, but this has not been parallelled by a similar reduction in mortality. We can speculate that in inflammatory disease states the mediators produced may prevent cells from using oxygen supplied to tissues, that is there exists a state of histotoxic hypoxia. This may explain why therapeutic efforts directed at increasing oxygen delivery to tissues have not resulted in improved outcome in SIRS.[24,25] If this hypothesis is correct then a different therapeutic approach is necessary.

Future management of acute brain injured patients may include pharmacological modification of the inflammatory processes involved in the pathophysiology of the condition, using antibodies or receptor antagonists, preventing further cell death and improving outcome.

# Ketamine increases the amplitude of the 40-Hz auditory steady-state response in humans†

G. PLOURDE, J. BARIBEAU AND V. BONHOMME

## Summary

The auditory middle latency response (AMLR) and the 40-Hz auditory steady-state response (40-Hz ASSR) are evoked potentials which possibly arise from the same generators in the primary auditory cortex. Both responses are attenuated by most general anaesthetics. Ketamine, however, has been reported to have no effect on the AMLR. Our aim was to evaluate the effects of ketamine on the 40-Hz ASSR. Spectral analysis of the electroencephalogram (EEG) was also conducted to independently examine the effects of ketamine. Ketamine 1.5 mg $kg^{-1}$ was given to 12 patients for induction of general anaesthesia. Recordings of the 40-Hz ASSR and EEG were obtained every minute from 3 min before administration of ketamine to 5 min after injection, when the study was terminated. Similar recordings were obtained in three control subjects under identical conditions except that no medication was administered. Consciousness, defined as responsiveness to verbal commands, was assessed before each recording. Ketamine caused an *increase* in the amplitude of the 40-Hz ASSR ($P<0.01$). Using published AMLR data, we conducted a simulation experiment that suggested that the effect of ketamine on the AMLR can explain its effects on the amplitude of the 40-Hz ASSR. There was a pronounced increase in relative theta (3.9–7.9 Hz) EEG power and a decrease in relative alpha (8.0–12.8 Hz) power ($P<0.001$). These changes were not observed in the control group. Ketamine produced unconsciousness until the end of the study in five patients and transient unconsciousness in five patients. Two patients did not lose consciousness after administration of ketamine. The 40-Hz ASSR and EEG revealed no consistent differences between conscious and unconscious patients. No relationship could be demonstrated between the increase in amplitude of the 40-Hz ASSR or of relative theta power (the hallmark of ketamine effect) and loss of responsiveness to commands. We conclude that ketamine, unlike other anaesthetics, *increases* the amplitude of the 40-Hz ASSR. (*Br. J. Anaesth.* 1997; **78**: 524–529).

**Key words**

Anaesthetics i.v., ketamine. Brain, evoked potentials. Monitoring, evoked potentials. Anaesthesia, depth.

The auditory middle-latency response (AMLR)[1] and the 40-Hz auditory steady-state response (40-Hz ASSR)[2] are affected by general anaesthetics. Both responses are auditory evoked potentials, that is changes in the electrical activity of the brain caused by auditory stimuli. The AMLR and the 40-Hz ASSR probably arise from the same generator in the primary auditory cortex.[3] Differences between the two responses depend on the rate of stimulus delivery. The AMLR is a *transient* evoked response. Transient responses are evoked by stimuli presented at a rate sufficiently slow so that the response to one stimulus is over before the next stimulus occurs. The 40-Hz ASSR is a *steady-state* response. Steady-state responses are evoked by stimuli presented so rapidly as to cause overlapping of the responses to successive stimuli.[4]

Schwender and colleagues[5] recently examined the effect of ketamine 2 mg $kg^{-1}$ on the AMLR during induction of general anaesthesia. They concluded that ketamine had no effect on the AMLR. The effects of ketamine on the 40-Hz ASSR have not been studied. The aim of this study was to measure the effect of ketamine 1.5 mg $kg^{-1}$ on the 40-Hz ASSR. It was not possible to concurrently record the AMLR but the EEG was recorded to document independently the effects of ketamine.

## Patients and methods

The study was approved by the institutional Ethics Committee. We studied 12 ASA I elective surgical patients, aged 18–50 yr (mean 33 yr), who gave written informed consent. All were within the ideal body weight range (Metropolitan Weight Tables, 1983), denied past neurological or otological disease and had normal otoscopy. No premedication was given. After insertion of an i.v. cannula into the left arm and placement of monitors (ECG, arterial pressure cuff and pulse oximetry probe) patients breathed oxygen by face mask for 3 min. Three

baseline recordings of the 40-Hz ASSR were obtained, one every minute. Ketamine (Ketalar) 1.5 mg $kg^{-1}$ was given over 15 s and the 40-Hz ASSR recorded every 1 min for 5 min, starting with the beginning of injection. Before each recording the level of consciousness was assessed by asking the patient to squeeze the fingers of an observer unaware of the 40-Hz ASSR results. A patient who obeyed was considered conscious.

At 5 min after administration of ketamine, the study was terminated. Midazolam 0.1 mg $kg^{-1}$ and thiopentone 3 mg $kg^{-1}$ were given before proceeding with standard anaesthetic care. While in the recovery room after surgery, patients were asked to describe what they remembered from the induction period.

To verify the stability of the responses, recordings were obtained in three volunteers (aged 30–40 yr) under identical conditions except that the i.v. cannula was only taped to the skin, rather than inserted into a vein, and no medication was administered.

A microcomputer (Intel 80386 processor) was used for controlling stimulus delivery and recording the electroencephalogram (EEG). Stimuli were 500 Hz tonebursts (10 ms duration; 2 ms rise and fall time; 84 dB peak equivalent sound pressure level) delivered binaurally at a rate of 40 $s^{-1}$ via insert earphones ("E-A-R TONE" 3A, Cabot Corporation, Indianapolis, IN, USA). The stimulus waveform (gated continuous sine wave) was created by the microcomputer, fed through a digital-to-analogue (D/A) converter (D/A rate 20 kHz) and attenuated before reaching the earphones to obtain 84 dB.

The EEG was recorded from Cz[6] with gold-plated cup electrodes filled with conductive gel. The reference was the right mastoid and the ground was on the back of the neck over the fifth cervical vertebra. Impedances were maintained at less than 3 kΩ (at 30 Hz). The EEG was amplified (amplifier model 12A5, Grass Instruments Co., Quincy, MA, USA) with a bandpass of 0.3–100 Hz. The analogue-to-digital (A/D) sampling rate was 298.978 Hz with 1024 data points per channel, yielding an epoch duration of 3.425 s. The A/D resolution was 12 bits. Epochs contaminated by excessive artefacts were rejected. The criterion for rejection was 10% or more data points exceeding +100 μV. Epochs were averaged by groups of 10.

## MEASUREMENTS

### *40-Hz ASSR*

Amplitude (baseline to peak) and phase (sine function) at 40 Hz were obtained by computing the fast Fourier transform (FFT)[7] of the averaged waveforms. No windowing was used because the choice of the sampling frequency ensured that there would be an FFT term exactly at 40 Hz.

### *EEG*

Because averaging uniformly attenuates all frequencies, it is possible to obtain an estimate of the power spectrum of the EEG from the averaged waveforms.[8] The presence of evoked activity (40-Hz ASSR) does not interfere with this process, because it is outside the frequency range used for EEG analysis.[8] Power from 30.0 to 38.0 Hz and from 42.0 to 50 Hz was first measured to estimate absolute gamma band power. The 38.0–42.0 Hz range was omitted to avoid contamination by the 40-Hz ASSR. A non-phase shift FFT-based digital filter[7] was used to remove residual noise below 1.5 Hz and above 30 Hz. The power spectrum of the averaged waveforms was computed by FFT with a Hanning window. Absolute power in the following frequency bands was measured: delta (1.5–3.8 Hz), theta (3.9–7.9 Hz), alpha (8.0–12.8 Hz), beta 1 (12.9–19.9 Hz) beta 2 (20.0–30.0 Hz) and gamma (30.0–38.0 Hz and 42.0–50 Hz). Relative power for each band was obtained by dividing absolute power by total power (1.5–30 Hz plus gamma band).

## STATISTICAL ANALYSIS

When required, data were log transformed to meet the normality assumption (Lilliefors test).[9] Analysis of variance (ANOVA) for repeated measures with six levels (baseline, the average of the three baseline recordings and the 0-, 1-, 2-, 3- and 4-min recordings) was used. The least significant difference (LSD) test was used for planned *post hoc* comparison (baseline *vs* each subsequent recording).[10] The Pearson product moment correlation coefficient[11] was used to evaluate the relationships between variables at each assessment time. The Lilliefors test was carried out with the program Systat (version 5.2.1 for Macintosh) (SPSS Inc, Chicago, IL, USA). All other procedures were carried out with CSS Statistica (version 3.1 for DOS) (Statsoft Inc, Tulsa, OK, USA). The criterion for significance was $P<0.01$. All differences approaching significance ($0.01<P<0.05$) are indicated.

## PREDICTING THE EFFECTS OF KETAMINE ON THE 40-HZ ASSR FROM ITS EFFECTS ON THE AMLR

It is reasonable to assume that in awake subjects the 40-Hz ASSR can be predicted from the AMLR by superposition.[12–14] It was not possible to concurrently record the AMLR. The effects of ketamine 2 mg $kg^{-1}$ on the AMLR have been described by Schwender and colleagues.[5] Although these authors found no change in the amplitude and latencies of the peaks of the AMLR, inspection of their waveforms suggests that ketamine enhanced near 40-Hz oscillations occurring 40–80 ms after the stimulus. We have used the data of Schwender and colleagues[5] to study the effect of ketamine on the amplitude of the 40-Hz ASSR.

Figures 1 and 2 from Schwender and colleagues[5] were digitized with a flat-bed high resolution (600 dpi) scanner. The resulting bitmap images were traced manually with Corel Draw (version 2.0, Corel Draw Corporation, Ottawa, Canada). Each traced waveform was exported as a HPGL (Hewlett-Packard graphics language) file.[15] The HPGL file contains the X-Y coordinates of the waveform. Cubic spline interpolation[7] was used to obtain measurements from 0 to 99 ms in 1-ms steps. Visual inspection showed that the recovered waveforms were virtually identical to the originals from the article by Schwender and colleagues.[5] The predicted 40-Hz ASSR waveform was computed from the recovered AMLR by summation of the four 25-ms segments of the AMLR (0–24, 25–49, 50–74 and 75–99 ms) (See Plourde and Villemure[16] for a complete description of the computation.) The amplitude of the predicted ASSR was obtained by FFT.

## Results

### 40-HZ ASSR

There was a decrease in amplitude for the recording started concurrently with administration of ketamine ($t=0$ min, $P<0.05$) followed by a progressive increase in amplitude ($P<0.01$ at $t=3$ min) (table 1, fig. 1). For phase, there was a sudden increase for the recording started 1 min after administration ($P<0.001$). Phase remained significantly higher than baseline afterwards, despite a progressive decline towards baseline values (table 1, fig. 1). The control subjects showed no amplitude or phase changes with time.

### EEG

Three variables showed significant changes after administration of ketamine: relative power in the alpha, beta 1 and theta frequency bands (table 1, fig. 2). There was a significant ($P<0.001$) decrease in relative alpha power for the recording started 3 min after injection. Relative beta 1 power also decreased significantly ($P<0.01$) from 1 min onwards after injection. There was a very pronounced and highly significant ($P<0.001$) increase in relative theta power from 1 min after injection. Relative alpha and theta power remained stable over time in the three control subjects. Relative beta 1 power however decreased by approximately 30% in the controls (compared with approximately 50% in patients).

There was a modest decrease in relative delta power after ketamine but the difference was not significant ($P=0.18$, ANOVA). Relative power in beta 2 and gamma bands remained stable over time in patients and control subjects (fig. 2).

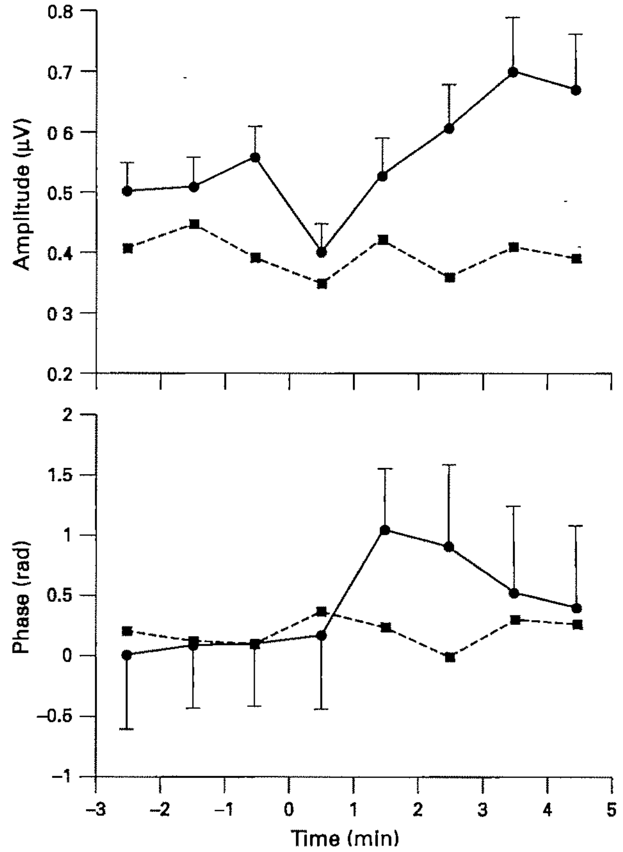

*Figure 1* Amplitude and phase of the 40-Hz ASSR. ●=Mean, SEM for patients ($n=12$); ■=mean for control subjects ($n=3$). Each datum point represents 34.25–47.95 s (depending on the number of rejected epochs, 0–4) of recording time, starting at the beginning of the interval where the point is plotted. Ketamine was given at time 0.

### RESPONSIVENESS TO VERBAL COMMANDS

Responsiveness to verbal commands was assessed *before* each recording. All patients were responsive for the baseline recordings and for recording during which ketamine was administered. Five patients became unresponsive for the four recordings started after administration of ketamine. Two patients remained responsive for all recordings after injection. Five patients remained responsive for one or two of the four recordings after injection. There were no differences between the five patients who remained unresponsive during all recordings after injection and two patients who remained responsive throughout, with regard to amplitude (fig. 3) and phase of the 40-Hz ASSR or to any EEG variables. Even during unresponsiveness to commands, patients' eyes frequently remained intermittently open and the eyelash reflex to touch was present. No patient had any recollection of events after administration of ketamine.

### PREDICTED 40-HZ ASSR FROM THE AMLR DATA OF SCHWENDER AND COLLEAGUES[5]

The amplitude of the predicted 40-Hz ASSR is shown in table 2. The 40-Hz ASSR predicted from the grand average waveforms from Schwender and colleagues[5] (their fig. 2, based on 20 patients) was

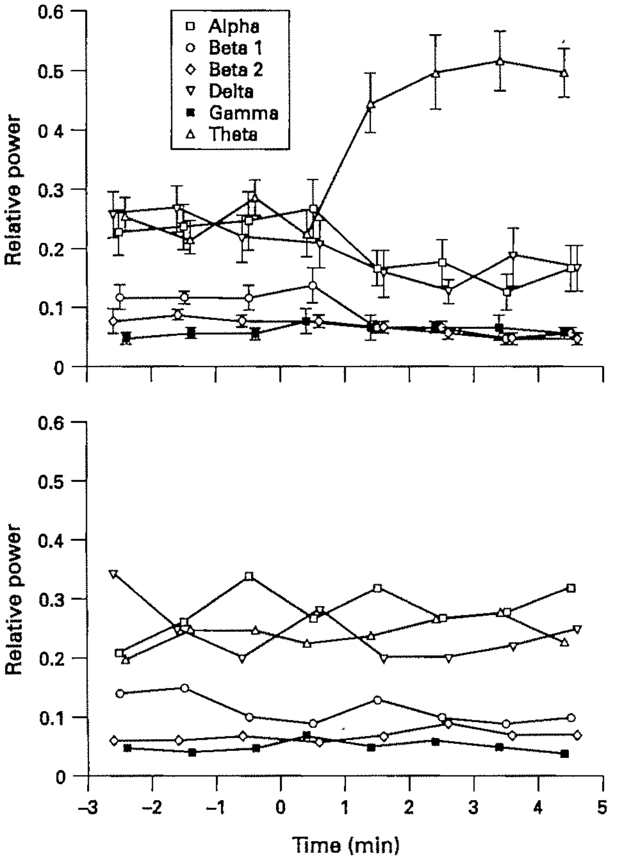

*Figure 2* Relative power for each frequency bands. Each datum point represents 34.25–47.95 s (depending on number of rejected epochs), starting at the beginning of the interval where the point is plotted. Ketamine was given at time 0. A small horizontal offset was used for clarity. Top: results for patients ($n$=12; mean, SEM); bottom: results for controls ($n$=3; mean only because of small sample size).

*Table 2* Relative amplitude of the 40-Hz ASSR predicted from the data reported by Schwender and colleagues.[5] The grand average data are from their figure 2. Patients 1–4 are from their figure 1, with patients numbered clockwise

| | Grand average | Patient No. 1 | Patient No. 2 | Patient No. 3 | Patient No. 4 |
|---|---|---|---|---|---|
| Baseline | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| 0–2 min | 1.42 | 1.15 | 1.75 | 1 15 | 1.95 |
| 2–4 min | 1.25 | 0.99 | 1.67 | 1.09 | 1.48 |
| 4–6 min | 1.50 | 0.78 | 1.53 | 0.55 | 1.20 |

increased by 25–50% for up to 6 min after ketamine. An increase in the amplitude of the predicted 40-Hz ASSR was also noted on the recordings obtained 0–2 min after ketamine for all four patients shown in figure 2 of Schwender and colleagues.[5] A comparable increase was also noted with two of the four patients on the recordings obtained 2–4 min and 4–6 min after ketamine.

## Discussion

Unlike other anaesthetics,[17] ketamine *increased* the amplitude of the 40-Hz ASSR. This observation, though somewhat surprising, was not completely unexpected. The recordings of Schwender and colleagues[5] raised the possibility that ketamine could have a facilitatory role on 40 Hz oscillations after auditory stimuli (see their fig. 2 which shows a new wave occurring 50–70 ms after the stimulus on the recording performed 4–6 min after administration of ketamine). Domino, Chodoff and Corssen[18] observed increased amplitude of the middle latency somatosensory response evoked by electrical

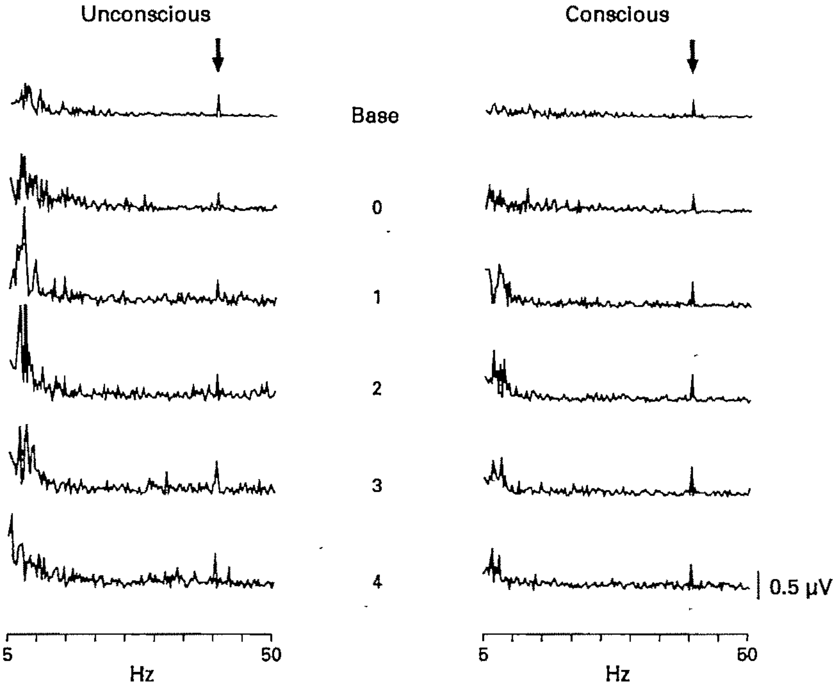

*Figure 3* Amplitude spectra from two patients. The tracings on the left are from a patient who was unconscious before the recordings started, 1–4 min after ketamine. Tracings on the right are from a patient who remained conscious for all recordings. The numbers indicate time (in minutes) when the recording was started relative to administration of ketamine (time 0). The baseline (base) spectra were obtained by computing the fast Fourier transform of the average of the three baseline recordings. The 40-Hz ASSR peak is indicated by the arrows. There was an increase in the 40-Hz amplitude at 3 and 4 min for both patients. Part of low frequency power for the left tracings at 2 min has been clipped to save vertical space.

stimulation of the median nerve. Schultz and colleagues[19] and Schwartz, Virden and Scott[20] showed that ketamine increased spontaneous EEG activity in the 25–45 Hz range. Spontaneous fast (30–40 Hz) rhythms have been recorded during anaesthesia with ketamine and xylazine (an $\alpha_2$ agonist for veterinary use) in thalamocortical networks of cats[21] and in the hippocampus of rats.[22]

Simulation of the 40-Hz ASSR using the data of Schwender and colleagues[5] suggested that the effect of ketamine on the AMLR can explain its effect on the amplitude of the 40-Hz ASSR. The demonstration was particularly convincing for the grand average data from Schwender and colleagues[5] (table 2). An increase in the amplitude of the predicted 40-Hz ASSR was also noted with the four individual subjects from Schwender and colleagues[5] for the recording obtained 0–2 min after administration of ketamine. In two subjects, the increase in amplitude persisted until the last recording, obtained 4–6 min after ketamine. With simulation experiments, we place more emphasis on grand average rather than individual data, because the prediction process works best when there is minimal residual noise. We must acknowledge, however, that the time course of the increase in amplitude of the 40-Hz ASSR observed in this study occurred later than that predicted by the grand average data from Schwender and colleagues.[5] The most likely explanation is the difference in the dose of ketamine between the two studies.

Another possible explanation for the increased 40-Hz ASSR amplitude after ketamine is to view the auditory system as a tuned oscillator[12] with an optimal resonance frequency of 37–38 Hz[23] and to propose that ketamine brings this optimal frequency closer to 40 Hz without changing the AMLR. At present we see no need for this explanation because our reconstruction experiment strongly suggested that the increased 40-Hz ASSR amplitude after ketamine can be explained by superposition of the AMLR.

We did not observe an increase in relative EEG gamma power, as anticipated from the observations of Schultz and colleagues[19] and Schwartz, Virden and Scott.[20] There are two possible explanations. We administered a smaller dose of ketamine (1.5 mg $kg^{-1}$) than Schultz and colleagues (2–3 mg $kg^{-1}$) and Schwartz, Virden and Scott (2 mg $kg^{-1}$). We used averaged EEG traces (based on 10 epochs) for estimation of relative power. Transient modest increases in gamma activity during 2 or 3 epochs would probably be missed by using averages. However, we do not believe that exclusion of the 38–42 Hz range, which contained the 40-Hz ASSR, can explain the absence of the increase in gamma power.

In common with previous investigators, we observed a marked increase in theta power, the hallmark of the EEG effects of ketamine,[18-20] and a decrease in alpha power.[24] The beta 1 power band had not been specifically examined before. We noted a 50% decrease in beta 1 power after ketamine but the three control subjects showed a decrease of 30%. Further observations are required to clarify the effect of ketamine on beta 1 power. This question could perhaps have been resolved if we had studied a larger control group. Our primary motive for testing control subjects was, however, to exclude the remote possibility that the amplitude of the 40-Hz ASSR increases with repeated testing. Because a first group of three control subjects revealed no evidence of amplitude increase with time, we felt that these results were sufficient to confirm the stability of the 40-Hz ASSR and that no further testing with control subjects was required.

A surprising finding was that the above changes of the 40-Hz ASSR and of the EEG were the same whether or not patients remained conscious. This observation differs from the report of Domino, Chodoff and Corssen[18] who indicated that theta activity was present only during unconsciousness, being replaced by fast activity on return of consciousness. Domino, Chodoff and Corssen[18] defined consciousness as the ability to answer questions, a task more complex than following a simple command. The discrepancy between the observations of Domino, Chodoff and Corssen[18] and our own could be explained by the difference in how consciousness was assessed.

Finally, consideration must be given to how ketamine increases the amplitude of the 40-Hz ASSR and spontaneous gamma rhythms. Ketamine is considered a non-competitive antagonist of the *N*-methyl-D-aspartate (NMDA) receptor.[25 26] There is insufficient knowledge of the neurotransmitters involved in generation of the 40-Hz ASSR and spontaneous gamma rhythms to understand why antagonism of the NMDA receptor would enhance these rhythms. Our observations suggest however that the 40-Hz ASSR probably does not depend on NMDA receptors.

We conclude that ketamine, unlike other anaesthetics, increased the amplitude of the 40-Hz ASSR and that this effect can probably be explained by subtle alterations of the AMLR by ketamine.

## Acknowledgements

We thank S. Freiman for technical assistance and P. April for computer programming. This study was made possible by a clinical scholarship from the "Fonds de la recherche en santé du Québec" to G. P. and by grants from NSERC and from the Royal Victoria Hospital Research Institute.

# Effects of inotropes on human leucocyte numbers, neutrophil function and lymphocyte subtypes

A. M. BURNS, M. KEOGAN, M. DONALDSON, D. L. BROWN AND G. R. PARK

## Summary

We have investigated the effects of inotropes with different adrenergic receptor specificity on differential white cell count, lymphocyte subtypes and neutrophil function in healthy volunteers. Six healthy, male volunteers were enrolled into this randomized, placebo-controlled pilot study. Each volunteer was studied on four separate occasions during a 2-h infusion of various agents, and for 2 h after stopping the infusion. The agents investigated were adrenaline 0.1 $\mu g\ kg^{-1}\ min^{-1}$, dobutamine 5 $\mu g\ kg^{-1}\ min^{-1}$, dopexamine 2 $\mu g\ kg^{-1}\ min^{-1}$ and 5% glucose 0.5 $ml\ kg^{-1}\ h^{-1}$. Venous blood was sampled at 0, 30, 120 and 240 min. Haemodynamic monitoring was continued throughout the study. Full blood count, white cell differential count and enumeration of lymphocyte subtypes were performed. Neutrophil function tests included chemoluminescence, and assessment of neutrophil chemotaxis, phagocytosis and adhesion. The Wilcoxon signed rank test was used to compare differences between placebo and active drugs at each time compared with baseline. There was a significant increase in white cell count, lymphocyte count and neutrophil count with adrenaline, and a small but significant decrease in these variables with dobutamine and dopexamine. These changes were also apparent for absolute $CD3^+$, $CD4^+$ and $CD8^+$ lymphocyte counts. Neutrophil respiratory burst in response to f-methionyl-leucyl-phenylalanine increased significantly only with adrenaline at 30 min ($P$=0.046). There were no other significant changes in tests of neutrophil function. Infusion of inotropes was associated with changes in white cell numbers, lymphocyte subtypes and neutrophil respiratory burst. In healthy volunteers, adrenaline had effects different from those of dobutamine and dopexamine. The clinical relevance of such effects requires further investigation in critically ill patients. (*Br. J. Anaesth.* 1997; **78**: 530–535).

**Key words**
Blood, leucocytes. Blood, lymphocytes. Blood, neutrophils. Sympathetic nervous system, catecholamines.

There is increasing evidence to suggest that the neuroendocrine system interacts with, and is a potent modulator of, the immune system. Endogenous catecholamine release caused by stress induces leucocytosis.[1–3] Exercise increases both lymphocyte and neutrophil numbers,[2 4] but major surgical stress causes lymphopenia with polymorphonuclear leucocytosis.[1 5] Furthermore, increased release of cortisol accompanying stress, such as in major surgery, also affects leucocyte numbers.[6 7] Exogenous administration of adrenaline also induces leucocytosis with an initial increase in lymphocytes followed by neutrophilia and relative lymphopenia.[7–9]

Lymphocytes can be divided further into several subsets which include B lymphocytes, T lymphocytes and natural killer (NK) cells. Exercise-induced increases in adrenaline result in lymphocytosis, with a three-fold increase in cytotoxic T cells ($CD8^+$) and NK cells, and a smaller increase in helper T cells ($CD4^+$).[10 11] Exogenous administration of adrenaline alters the subtypes of lymphocytes: an increase in NK cells has been found consistently,[6 7 12 13] but although Brohee and colleagues[7] showed an increase in all lymphocytic subtypes, others have found that total T cell ($CD3^+$) and $CD4^+$ counts decreased.[6 12 13] This effect is thought to be caused by stimulation of $\beta_2$-adrenergic receptors on lymphocytes.[10 14 15] Prolonged exposure to catecholamines can lead to a reduction in the number of circulating lymphocytes in healthy volunteers.[16]

Catecholamines also affect white cell function. Administration of adrenaline has been shown to decrease neutrophil adherence *in vitro*,[13 17] decrease chemotaxis[18] and enhance NK activity.[6 12 19] Such changes in the immune system may be clinically important after major surgery, trauma and in the critically ill patient with sepsis.

The majority of studies in this field have been performed with adrenaline as the primary stimulant. Adrenaline stimulates $\alpha_1$-, $\beta_1$- and $\beta_2$-adrenergic receptors. In contrast, the synthetic inotropic agents dobutamine and dopexamine have no $\alpha_1$ agonist

activity. Dobutamine is a $\beta_1$- and $\beta_2$-adrenoceptor agonist,[20] while dopexamine stimulates dopaminergic and $\beta_2$- adrenoceptors, with minimal $\beta_1$-receptor activity.[21] Park, Couzens and Hoskins found that total white cell count increased during infusion of dopamine, dobutamine or dopexamine,[22] but little is known of the effects of these synthetic inotropic agents on white cell populations and function. The complexity of the interactions between the immune system and the neuroendocrine system make it unwise to extrapolate from studies with adrenaline to newer inotropic agents with different adrenergic receptor specificity. In view of the large number of immune variables thought to be affected by these agents, we chose to perform a pilot study. The aim of this study was to investigate the effects of inotropes with different adrenoceptor specificity on differential white cell count, lymphocyte subtypes and neutrophil function in six healthy volunteers.

## Subjects and methods

This pilot study was a placebo-controlled study of the effects of adrenaline, dobutamine and dopexamine on white cell count, lymphocyte subtype count and neutrophil function in healthy volunteers. Volunteers were studied on four different occasions, each at least 1 week apart. All studies started between 08:00 and 09:30 to avoid confounding effects of circadian rhythms on the variables measured. Each volunteer was allocated randomly to receive the different agents in a different order. Volunteers and laboratory investigators, but not the clinical investigator, were blinded to the drug administered. Approval from the local District Ethics Committee was obtained.

We studied six healthy male volunteers. Before recruitment, any volunteer with a history of chronic illness, receiving treatment for intercurrent illness, a history of drug or alcohol (>25 units/week) abuse or cigarette smoking, or known allergy to inotropic agents was excluded. Written informed consent was obtained from each volunteer and a full physical examination with laboratory and electrocardiographic assessment was performed by an independent physician, before and at the end of the study.

### INOTROPE ADMINISTRATION

The study was conducted in an area which had full resuscitation facilities and a physician in attendance at all times. A 16-gauge cannula was inserted into each forearm under local anaesthesia: one cannula was used for blood sampling and the other for administration of the test substance only. Haemodynamic monitoring with continuous ECG and an automatic intermittent arterial pressure monitoring device was then started. After a baseline reading, arterial pressure was measured at 2 and 5 min after starting the infusion, and then at 5-min intervals throughout the infusion and the 30-min period after the infusion was stopped. Additional readings were obtained at 3 and 4 h after starting the study. Volunteers remained recumbent throughout the study. Coffee or tea was avoided for 8 h before the study, and only orange squash, toast and biscuits were allowed throughout the study.

Volunteers were studied during a 2-h infusion, and for 2 h after completion of the study. The agents investigated were adrenaline 0.1 $\mu g\ kg^{-1}\ min^{-1}$, dobutamine 5 $\mu g\ kg^{-1}\ min^{-1}$, dopexamine 2 $\mu g\ kg^{-1}\ min^{-1}$ and 5% glucose 0.5 $ml\ kg^{-1}\ h^{-1}$ as placebo. The infusion rate was halved or stopped if heart rate exceeded 120 beat $min^{-1}$, arrhythmia developed or mean arterial pressure changed by more than 20 mm Hg.

Venous blood was sampled before starting the infusion ($t$=0), at 30 and 120 min after starting the infusion, and 2 h after stopping the infusion. A maximum of 30 ml of blood were required at each sampling time: 20 ml of heparinized blood for neutrophil studies, 2×2.7 ml in EDTA for differential white cell count and lymphocyte subtypes, and 5 ml of spare serum in the event of further tests being required to validate results. Differential white count and lymphocyte subtypes were measured at all four times, and neutrophil function was measured at 0, 30 and 120 min.

### MEASUREMENT OF HAEMATOLOGICAL AND IMMUNOLOGICAL VARIABLES

A full blood count and white cell differential count were performed using a STK-S Coulter counter (Coulter Electronics, UK). Where an automated white cell differential count could not be obtained, a manual white cell differential was performed.

Lymphocyte subtypes were assessed by dual colour immunofluorescence using a lysed whole blood technique. The markers used were $CD19^+$ (B cells), $CD3^+$ (total T cells), $CD4^+$ (T helper cells), $CD8^+$ (cytotoxic T cells), $CD3^+$/DR co-expression (activated T cells) and $CD16^+$ (NK cells). All reagents were from the Simulset range of monoclonal antibodies (Becton Dickinson, Oxford, UK). The percentage of each T cell subtype was measured by flow cytometry using a FACScan (Becton Dickinson, Oxford, UK) and Simulset software. Absolute values were calculated from this percentage and lymphocyte count from full blood count.

Blood for neutrophil function assays was obtained under pyrogen-free conditions into preservative-free heparin. All assays of neutrophil function were carried out under pyrogen-free conditions. The assays used do not require highly purified neutrophil populations, and so gravity sedimented leucocytes were used to avoid unnecessary manipulation of neutrophils.

Neutrophil respiratory burst in response to formyl-methionyl-leucyl-phenylalanine (fMLP) (Sigma, UK) was assessed using a luminol-enhanced chemoluminescence system. Phagocytosis of both opsonized and unopsonized zymosan was assessed indirectly, using a luminol-enhanced chemoluminescence system. The chemotactic response (directional movement of neutrophils towards a stimulus with chemoattractant properties) together with chemokinesis (non-directional, random neutrophil motility) was assessed under agarose.[23] The chemotactic responses to different stimuli (fMLP, autologous serum, zymosan-activated serum and normal pooled human serum) were tested. Neutrophil adhesion to protein-coated glass was assessed by microscopy in a chamber assay.[24] The expression of CD11b, a component of the CD11b/CD18 integrin adhesion molecule, was measured by flow cytometry.

### STATISTICAL ANALYSIS

As all of the immunological variables measured vary greatly both within- and between-individuals, changes during each study were expressed as percentage change from baseline (measurement at $t=0$). Results are expressed as mean (SEM) percentage change from baseline where $n=6$. The Wilcoxon signed rank test was used to compare differences between placebo and active drugs on changes from baseline at each time.

## Results

All six volunteers completed the four study periods. The infusion rate was halved only once, when mean arterial pressure decreased by greater than 20%, 5 min after an infusion of adrenaline was started. Arterial pressure then returned to baseline values. On all other occasions heart rate and mean arterial pressure remained within the predetermined limits. No arrhythmias occurred. Volunteers noted a variety of subjective sensations, including tremor, headache and awareness of the heart beating, but they were not distressed by these symptoms.

Data for all variables were obtained, except in the following instances: monocyte and basophil counts were not obtained for one study because of a technical problem with the Coulter counter, and platelet count was not obtained for all four studies in one volunteer because of platelet clumping. This is a problem which can occur in normal individuals and did not signify any significant underlying disease.

### HAEMATOLOGICAL VARIABLES

Mean percentage changes from baseline for differential white cell count and lymphocyte subtypes that occurred during infusion of each of the four agents at each time, and the significance of these changes compared with placebo, are shown in tables 1 and 2, respectively. Infusion of adrenaline was associated with significant leucocytosis, lymphocytosis and neutrophilia, whereas infusions of dobutamine and dopexamine were associated with a significant decrease in white cell, lymphocyte and neutrophil counts. These changes were also apparent for absolute CD3$^+$ count (total T cells), absolute CD4$^+$ count (helper T cells) and absolute CD8$^+$ count (cytotoxic T cells). Monocytes increased significantly only during infusion of adrenaline, whereas eosinophil count increased initially with infusion of adrenaline, and then decreased with infusion of all three agents. There were no significant changes in haemoglobin, packed cell volume or red cell count. Platelet count increased significantly with infusion of adrenaline compared with placebo at 30 ($P=0.043$) and 120 min ($P=0.043$).

### NEUTROPHIL FUNCTION

Mean percentage changes from baseline for the neutrophil function tests that occurred with infusion of each of the four agents at each time, and the significance of these changes compared with placebo, are shown in table 3. There was a significant increase in chemoluminescence with infusion of adrenaline for 30 min compared with placebo ($P=0.046$). Neutrophil adhesion, CD11b expression and phagocytosis were not changed significantly by infusion of any of the test drugs at the given dose. Chemotaxis (directional neutrophil movement) to fMLP, the volunteer's own serum, normal human serum and zymosan-activated serum did not change significantly. Chemokinesis (non-directional random

movement) increased significantly 30 min after infusion of dobutamine compared with placebo ($P=0.03$). However, as chemotaxis was unaffected, this effect is unlikely to be clinically relevant.

## Discussion

We found a significant increase in white cell count, lymphocyte count and neutrophil count with adrenaline, and a small but significant decrease in these variables with dobutamine and dopexamine. These trends were also apparent for absolute CD3$^+$, CD4$^+$ and CD8$^+$ counts. Chemoluminescence increased significantly only with adrenaline, and there were no other significant changes in tests of neutrophil function.

Leucocytosis, lymphocytosis and neutrophilia in association with exogenous administration of adrenaline is well recognized. Changes in circulating leucocyte numbers may be caused by an absolute change in total leucocyte count or alteration in the fraction of leucocytes present in the circulation. Two populations of neutrophils have been identified: circulating and marginal. Adrenaline appears to mobilize the marginating pool into the circulating pool without altering the total neutrophil population.[25] After major surgical stress lymphopenia is associated with redistribution of lymphocytes from the blood to lymphatic tissue.[26] Of interest was the significant decrease in white cell numbers, lymphocyte and neutrophil counts which was evident during infusion of the synthetic agents dobutamine and dopexamine. These trends were also apparent for absolute $CD3^+$ count (total T cells), absolute $CD4^+$ count (helper T cells) and absolute $CD8^+$ count (cytotoxic T cells). All three agents increased natural killer cell count, as has been described previously with adrenaline. These changes are of interest, but are difficult to interpret in a clinical setting as they probably reflect transient changes in the intravascular pool which may not reflect events in the tissues. Our results are in contrast with the increase in white cell count seen with infusion of dobutamine or dopexamine in the study by Park, Couzens and Hoskins,[22] which may reflect the higher doses of these agents used in their study. The differences between adrenaline and the synthetic inotropes may reflect the different $\beta_2$-adrenergic activity of the agents, despite the doses being chosen with a view to equipotency. However, each volunteer has a different pharmacodynamic response to each agent, depending on factors such as the concentration of endogenous circulating catecholamines, and variation between individuals for a given dose may account in part for the differences seen.

The numbers of monocytes increased only during infusion of adrenaline, whereas eosinophil count increased initially with infusion of adrenaline, and then decreased with infusion of all three agents. These changes probably reflect changes in the white cell populations between circulating and marginal pools. A significant increase in platelet count was seen only with adrenaline. Adrenergic stimulation increases platelet numbers and activation, while $\beta_2$-adrenergic stimulation decreases platelet numbers and platelet aggregation.[27 28] The effect of adrenaline was caused presumably by $\alpha$-adrenergic stimulation; neither dobutamine nor dopexamine possess $\alpha$-agonist activity. It is important that clinicians recognize such effects when interpreting laboratory data from patients receiving these agents, as this may avoid unnecessary investigation of drug-related changes.

The effect of infusion of adrenaline on chemoluminescence is of interest, suggesting an increase in the generation of reactive oxygen species by the neutrophil. However, another possible explanation is that the marginating neutrophil pool mobilized by adrenaline may be of a functionally more active group of neutrophils. The role of neutrophil activation resulting in increased free radical production and direct tissue damage in the pathophysiology of multiple organ failure and acute lung injury is well recognized.[29 30] In view of the widespread use of inotropes, the relevance of neutrophil activation in patients would certainly be worthy of further study. As adrenaline, dobutamine and dopexamine infusions had no effect on neutrophil chemotaxis, it is unlikely that the acute effect of dobutamine on chemokinesis is clinically important.

This preliminary study was designed to identify specific variables which could then be studied on a larger scale in both volunteers and specific patient populations. The problems associated with determining a normal range for lymphocyte subsets and neutrophil function are reduced by using volunteers as their own controls. While a small study in which so many variables are measured is likely to show some statistically significant results, further work is required to determine which of these results is clinically important.

In summary, this study suggests that infusion of inotropes was associated with changes in white cell numbers, lymphocyte subsets and neutrophil respiratory burst. Adrenaline had effects different from those of the synthetic inotropic agents, dobutamine and dopexamine, at least in healthy volunteers. The study highlighted areas in which further work is needed to determine the clinical relevance of immunological effects of different inotropic agents.

## Acknowledgements

This work was supported by a grant from the East Anglian Regional Health Authority. We are grateful for the assistance of the Departments of Haematology and Biochemistry, Addenbrooke's NHS Trust, the staff of the intensive care unit, and Dr David Olivera and Dr David Wilks for acting as independent physicians. We are also grateful to Dr W. Gilks of the MRC Biostatistics Unit, Cambridge and Dr P. M. E. Altham of the Department of Pure Mathematics and Mathematical Statistics, University of Cambridge, for their advice on study design and statistical analysis.

# Can prolonged expiration manoeuvres improve the prediction of arterial $P\text{CO}_2$ from end-tidal $P\text{CO}_2$?

B. TAVERNIER, D. REY, D. THEVENIN, J.-P. TRIBOULET AND P. SCHERPEREEL

## Summary

We have studied, in 16 patients undergoing thoracoabdominal oesophagectomy, if two prolonged expiration manoeuvres improve prediction of arterial $P\text{CO}_2$ ($Pa_{\text{CO}_2}$) from end-tidal $P\text{CO}_2$ ($P\text{E}'_{\text{CO}_2}$). $P\text{E}'_{\text{CO}_2}$, $P\text{CO}_2$ at the end of a simple prolonged expiration ($P\text{E}_{1\,\text{CO}_2}$), and $P\text{CO}_2$ at the end of a prolonged expiration preceded by sustained hyperinflation of the lungs ($P\text{E}_{2\,\text{CO}_2}$), were measured during laparotomy, in the lateral thoracotomy position during two-lung ventilation, and after transition to one-lung ventilation. ($Pa_{\text{CO}_2}-P\text{E}'_{\text{CO}_2}$) was 1.3 (SD 0.4) kPa during laparotomy and this remained stable throughout the study. Both manoeuvres decreased the mean arterial to peak expired $P\text{CO}_2$ difference, particularly during one-lung ventilation. However, $P\text{E}_{1\,\text{CO}_2}$ and $P\text{E}_{2\,\text{CO}_2}$ did not agree more closely with $Pa_{\text{CO}_2}$ than $P\text{E}'_{\text{CO}_2}$ at any stage of the study. We conclude that these manoeuvres did not improve estimation of $Pa_{\text{CO}_2}$ from $P\text{E}'_{\text{CO}_2}$. (*Br. J. Anaesth.* 1997; **78**: 536–540).

Continuous measurement of end-tidal carbon dioxide partial pressure ($P\text{E}'_{\text{CO}_2}$) has long been used for non-invasive estimation of arterial $P\text{CO}_2$ ($Pa_{\text{CO}_2}$) during anaesthesia.[1,2] However, a major concern is that $P\text{E}'_{\text{CO}_2}$ generally underestimates $Pa_{\text{CO}_2}$, with variations both between and within subjects.[3–5] The arterial to end-tidal $P\text{CO}_2$ difference ($Pa_{\text{CO}_2}-P\text{E}'_{\text{CO}_2}$) depends on the spread of ventilation–perfusion ratios. One index of an increased spread of ventilation–perfusion ratios is an increased slope of the "expiratory plateau" of the single breath test (expired carbon dioxide plotted against expired volume).[6] Thus individuals with an increased phase III slope on the capnogram often have an increased arterial to end-tidal $P\text{CO}_2$ difference.[4] During controlled ventilation in adults, the "expiratory plateau" is usually flat and nearly horizontal, but several factors, such as age and airways disease, and in particular smoking, are associated with an increase in the slope of the "expiratory plateau".[5,6] In this situation, the $P\text{E}'_{\text{CO}_2}$ value cannot be taken as a good estimate of alveolar $P\text{CO}_2$ and hence not as an estimate of $Pa_{\text{CO}_2}$. In this case, a simple prolonged expiration (permitting expiration to continue for 5–15 s) or a forced expiration (induced by a gentle squeeze on the patient's chest) may give a more representative estimation of $Pa_{\text{CO}_2}$.[7,8] Thus these manoeuvres are currently recommended to improve prediction of $Pa_{\text{CO}_2}$ from $P\text{E}'_{\text{CO}_2}$, especially when a steeply sloping "plateau" is observed.[9,10] However, the validity and usefulness of these measurements in individual patients have not been investigated.

Patients with oesophageal carcinoma are almost exclusively smokers with resultant airways disease. Their ($Pa_{\text{CO}_2}-P\text{E}'_{\text{CO}_2}$) and the phase III slope of their capnogram would thus be expected to be increased during anaesthesia, especially during thoracotomy.[11,12] We have therefore studied in patients undergoing thoracoabdominal oesophagectomy two prolonged expiration manoeuvres in order to assess if this improves prediction of $Pa_{\text{CO}_2}$ from $P\text{E}'_{\text{CO}_2}$.

## Patients and methods

We studied 16 successive patients (14 males), mean age 60 (range 48–71) yr, undergoing thoracoabdominal oesophagectomy for cancer. All patients were devoid of symptomatic cardiac disease. Fourteen were smokers. Lung function tests ($\text{FEV}_1$, FVC) were performed before operation. The study was approved by the Ethics Committee of our University Hospital and all patients gave informed consent.

Patients were premedicated with hydroxyzine 100 mg orally, 90 min before induction of anaesthesia with fentanyl 5 $\mu$g kg$^{-1}$ and thiopentone 5 mg kg$^{-1}$. Pancuronium 0.1 mg kg$^{-1}$ was administered to produce neuromuscular block and facilitate tracheal intubation. Anaesthesia was maintained with fentanyl, and enflurane with 50% nitrous oxide in oxygen. Anaesthetic agents were administered as required to avoid variations in mean arterial pressure

>20% of baseline. Intraoperative monitoring consisted of continuous electrocardiography, pulse oximetry, direct arterial pressure measurement via a radial artery cannula and rectal temperature. For the abdominal procedure, the lungs were ventilated mechanically (Monnal D2 ventilator) at a ventilatory frequency of 12 bpm with a tidal volume of 10–12 ml $kg^{-1}$ and an inspiratory:expiratory (I:E) ratio of 1:2. After abdominal wound closure, a double-lumen endobronchial tube with a left-sided bronchial stem (Carlens tube) was sited for right thoracotomy. Endobronchial tube position and isolation of the two lumens were checked by auscultation, spirometry and respiratory gas detection with the patient in the lateral position. During one-lung ventilation (OLV), ventilatory settings were ventilatory frequency 15 bpm, tidal volume 8 ml $kg^{-1}$ and I:E ratio 1:2.

### PROLONGED EXPIRATION MANOEUVRES

To obtain a prolonged expiration, the ventilator was abruptly set, during one expiration, to spontaneous ventilation to permit expiration to continue for 10–20 s. Maximum concentration of expired carbon dioxide ($FE_1\ CO_2$) was then recorded. Values were considered valid when a well identified "plateau" was obtained. For the second manoeuvre, a 3-litre reservoir bag connected to the ventilator system was used. Lungs were inflated manually with fresh gases (oxygen and nitrous oxide) contained in the bag until airway pressure reached 35 cm $H_2O$. This pressure was held for 3 s, and then full expiration was permitted, with recording of maximum concentration of expired carbon dioxide ($FE_2\ CO_2$). Manoeuvres were performed in this non-randomized order because, in preliminary measurements, $FE_1\ CO_2$ increased when recorded immediately after $FE_2\ CO_2$.

### MEASUREMENTS

$Pa_{CO_2}$ was measured at 37 °C in duplicate (ABL 500 and 510, Radiometer), and values were corrected to the patient's temperature according to the following formula[13]:

$$Pa_{CO_2}=Pa_{CO_2}\,(37\,°C)-10^{0.019\,(T°-37)},$$

where $T°$=patient temperature. The differences between arterial and expired carbon dioxide partial pressures were calculated using temperature-corrected $Pa_{CO_2}$ values. End-tidal carbon dioxide fractions ($FE'_{CO_2}$, $FE_1\ CO_2$ and $FE_2\ CO_2$) were measured from gas sampled between the tracheal (or endobronchial) tube and the Y-piece of the ventilator tubing using a sidestream infrared capnometer (Capnomac Ultima, Datex) calibrated according to the manufacturer's instructions before use in each patient.[14] The capnograph traces were recorded (7041 M X-Y recorder, Hewlett-Packard) for analysis of the slope of the phase III of the capnograms. The "alveolar plateau" was arbitrarily considered normal (i.e. nearly horizontal) when the trace virtually did not increase in the final portion (last third) of the phase III of the capnogram. $PE'_{CO_2}$, $PE_1\ CO_2$ and $PE_2\ CO_2$ were obtained from $FE'_{CO_2}$, $FE_1\ CO_2$ and $FE_2\ CO_2$, respectively, according to the formula:

$$PCO_2=FCO_2-(Pb-PH_2O)$$

where Pb=barometric pressure and $PH_2O$=water vapour pressure at 37 °C. At each stage of the study, mean arterial pressure, heart rate and rectal temperature were measured. Blood was then sampled from the radial artery cannula for immediate $Pa_{CO_2}$ measurement. Syringes were rinsed with sodium heparin to prevent coagulation. Simultaneously, $FE'_{CO_2}$ was recorded. Then, $FE_1\ CO_2$ and $FE_2\ CO_2$ were obtained successively by appropriate manoeuvres. Finally, arterial blood was sampled for $Pa_{CO_2}$ measurement to verify stability of $Pa_{CO_2}$ during the procedure. The time necessary to obtain the entire set of measurements was <10 min.

Initial measurements were made during the abdominal procedure, before wound closure (T1). A second set of measurements was performed with the patient in the lateral position after 20 min with two-lung ventilation (TLV) (T2). After transition to OLV with the pleura open, measurements were repeated after an additional 20 min (T3) and 50 min (T4). A final set of measurements was obtained after wound closure, after 20 min with TLV, with the patient in the lateral position (T5).

### STATISTICAL ANALYSIS

Values of the differences between $Pa_{CO_2}$ and each end-expiratory carbon dioxide partial pressure (i.e. ($Pa_{CO_2}-PE'_{CO_2}$), ($Pa_{CO_2}-PE_1\ CO_2$) and ($Pa_{CO_2}-PE_2\ CO_2$)) were computed at each sample point, with results expressed as mean (SD). Differences were analysed using two-way analysis of variance for repeated measurements. Multiple comparisons were made with Fisher's protected least significant difference testing. $P<0.05$ was considered significant. To assess the usefulness of each prolonged expiration manoeuvre to improve estimates of $Pa_{CO_2}$ from end-expiratory $PCO_2$, mean values for arterial to end-expiratory $PCO_2$ differences were used as the mean error (or bias) of the method tested (i.e. $PE'_{CO_2}$, $PE_1\ CO_2$ and $PE_2\ CO_2$) relative to $Pa_{CO_2}$. The SD of the differences were used as the precision of the method tested. The mean range difference (2 SD) defined the 95% limits of agreement of each end-expiratory measure *vs* $Pa_{CO_2}$.[15]

## Results

Lung function tests ($FEV_1$, FVC) were not performed in two asymptomatic non-smoking patients.

A steep phase III slope without a good plateau was observed in the capnogram, and prolonged expiration manoeuvres clearly increased peak expired carbon dioxide partial pressure (with $PE_2$ $_{CO_2}$>$PE_1$ $_{CO_2}$).

Preoperative spirometry results were <80% of expected values in four of 14 patients (table 1). $Pa_{CO_2}$ was almost unchanged during each stage of the study in all patients (the larger variation observed in one set of measurements was 0.5 kPa). For analysis, $Pa_{CO_2}$ values before and after each set of measurements were averaged. Heart rate and mean arterial pressure were maintained within 20% of baseline when measurements were performed, and moderate progressive hypothermia was observed (from 37.2 (SD 0.3) °C at T1 to 36.2 (0.4) °C at T5).

Typical examples of capnographic traces obtained with both manoeuvres are shown in figure 1. At T1, $Pa_{CO_2}$ was 5.3 (0.6) kPa and $PE'_{CO_2}$ was 4.0 (0.5) kPa, and both remained unchanged throughout the study. As a result, ($Pa_{CO_2}$−$PE'_{CO_2}$), observed at T1, was 1.3 (0.4) kPa, and did not change significantly at each stage of the study (table 2). However, analysis of the capnograms showed that an almost horizontal phase III was obtained in 13 patients at T1, and in only eight patients at T2. Moreover, all patients had steep phase III slopes without a good plateau at T3 and T4 (and 13 patients at T5).

Both prolonged expiration manoeuvres decreased markedly the mean arterial to peak expired carbon dioxide partial pressure difference throughout the study, particularly during OLV: ($Pa_{CO_2}$−$PE_1$ $_{CO_2}$) and ($Pa_{CO_2}$−$PE_2$ $_{CO_2}$) were significantly smaller than ($Pa_{CO_2}$−$PE'_{CO_2}$) at T1 (0.8 (0.5) kPa and 0.6 (0.5) kPa, respectively, $P$<0.01 *vs* $PE'_{CO_2}$) and decreased further after transition to OLV (table 2). In addition, ($Pa_{CO_2}$−$PE_2$ $_{CO_2}$) was significantly smaller than ($Pa_{CO_2}$−$PE_1$ $_{CO_2}$) at each stage of the study (table 2); T3, T4 and T5 values were not significantly different from zero.

However, the manoeuvres did not reduce the variations in ($Pa_{CO_2}$−$PE'_{CO_2}$) observed between patients. The agreement between each end-expiratory $P$CO$_2$ and $Pa_{CO_2}$, as represented by the SD of the differences, was not improved with $PE_1$ $_{CO_2}$ or $PE_2$ $_{CO_2}$ compared with $PE'_{CO_2}$ at any stage of the study (table 2). To quantify the size of the measurement error that could be observed in clinical practice, data from all stages of the study were pooled. The 95% limits of agreement of $PE_1$ $_{CO_2}$ and $PE_2$ $_{CO_2}$ compared with $Pa_{CO_2}$ were −0.6 to 1.8 kPa and −1.0 to 1.4 kPa, respectively (and 0.5–2.1 kPa for ($Pa_{CO_2}$−$PE'_{CO_2}$)). This represented a range of values larger than 25% of the estimated value ($Pa_{CO_2}$) and thus were considered clinically unacceptable.

The two manoeuvres did not reduce the variations observed within patients. To illustrate this phenomenon, differences between the largest and smallest gradients obtained throughout the study were calculated patient by patient for the three end-expiratory carbon dioxide partial pressures. The results ranged from 0.3 to 1.0 kPa (mean 0.5 (SD 0.2) kPa), 0.3 to 2.0 kPa (1.0 (0.6) kPa) and from 0.5 to 1.8 kPa (1.0 (0.5) kPa) for ($Pa_{CO_2}$−$PE'_{CO_2}$), ($Pa_{CO_2}$−$PE_1$ $_{CO_2}$) and ($Pa_{CO_2}$−$PE_2$ $_{CO_2}$), respectively.

## Discussion

We undertook a study to see if two prolonged expiration manoeuvres improved estimation of $Pa_{CO_2}$ from $PE'_{CO_2}$ in patients undergoing oesophageal surgery, to achieve a wide range of ($Pa_{CO_2}$−$PE'_{CO_2}$) values with increased phase III slopes. None of the methods tested improved prediction of $Pa_{CO_2}$, even in situations which are currently recommended (i.e. a capnogram with a steeply sloping "alveolar plateau").

The ($Pa_{CO_2}$−$PE'_{CO_2}$) value is known to be increased in several situations.[1-5] In our study, the widened ($Pa_{CO_2}$−$PE'_{CO_2}$) observed at the end of the abdominal procedure was characterized by a flat and nearly horizontal plateau of the capnogram in 13 patients. This may suggest predominance of spatial ventilation–perfusion mismatching associated with a situation that does not influence pulmonary mechanical properties where well perfused and under perfused lung units empty simultaneously.[16] However, asynchronous emptying combined with increased ventilation–perfusion spread cannot be eliminated. Analysis of the phase III slope of the capnogram, contrary to the single breath test ($PCO_2$ plotted against expired volume), may not be a function of ventilation–perfusion spread. A horizontal plateau on the capnogram is likely to be a result of absence of expiratory gas flow at the sampling site of the carbon dioxide analyser.[16] As a result, a moderate decrease in mean ($Pa_{CO_2}-PE'_{CO_2}$) was obtained with the first prolonged expiration manoeuvre ($PE_1\ _{CO_2}$).

A steep phase III slope was observed at further stages of the study. Few studies have examined the slope of the phase III of the capnograms during thoracotomy. Our results suggest that an increased slope may be present frequently, particularly during OLV. This may be attributed to alterations in the spread of ventilation–perfusion ratios within the lungs related to prolonged anaesthesia,[17 18] increased vertical height of the lungs in the lateral decubitus position[19] and also OLV.[12 20] In addition, variations in the physiological deadspace fraction of tidal volume may occur during thoracic surgery, depending on many factors (especially variations in pulmonary arterial pressure[21]) which affect distribution of ventilation and perfusion within the lungs. Both within-units and between-units ventilation–perfusion mismatching may be improved by increasing tidal volume, at least if frequency is reduced at the same time.[4] The ventilatory settings used in this study were different from those in a previous study,[20] but the values of ($Pa_{CO_2}-PE'_{CO_2}$) were similar in both studies. The steep phase III slope and the dramatic decrease in mean ($Pa_{CO_2}-PE'_{CO_2}$) obtained with the simple prolonged expiration manoeuvre during thoracotomy, and particularly during OLV, strongly suggest the existence of delayed and asynchronous emptying, resulting in dynamic lung hyperinflation. Dynamic lung hyperinflation often occurs during OLV when a double-lumen endobronchial tube is used.[22] When exhalation is not complete, the areas with high ventilation–perfusion (and thus low $PCO_2$) are the most significant contributors to $PE'_{CO_2}$, inducing ($Pa_{CO_2}-PE'_{CO_2}$) to increase. The simple prolonged expiration manoeuvre ($PE_1\ _{CO_2}$) allows the low ventilation–perfusion, high $PCO_2$ areas to leave lungs and to make a more substantial contribution to end-expiratory $PCO_2$. If such a full expiration is preceded by sustained hyperinflation of the lungs ($PE_2\ _{CO_2}$ in this study), the extra ventilation is distributed preferentially to dependent, hypoventilated but well perfused lung regions.[23 24] The wash-out of areas with ventilation–perfusion ratios close to zero resulted in smaller, and frequently negative, ($Pa_{CO_2}-PE_2\ _{CO_2}$) gradients during OLV. In relatively healthy, non-pregnant adults, the incidence of negative ($Pa_{CO_2}-PE'_{CO_2}$) differences during controlled ventilation is 0–12% of patients,[5] but manual compression of the thorax (providing a "forced" $PE'_{CO_2}$) induces a decrease in ($Pa_{CO_2}-PE'_{CO_2}$) with a high incidence of negative gradients in patients with or without lung disease.[8] In addition, during OLV the dependent lung is small, thus each tidal breath is relatively effective in that it has a small functional residual capacity (FRC) to wash-out. This reduced FRC may have contributed to the negative differences during OLV.[5]

The manoeuvres did not reduce the variations observed with $PE'_{CO_2}$ both between and within patients. The intraoperative ($Pa_{CO_2}-PE'_{CO_2}$) relationship is complex and dynamic,[25] and the reduction of one factor (i.e. time-dependent ventilation–perfusion mismatching) obtained with the manoeuvres did not reduce these variations. The decrease in arterial to end-expiratory difference obtained with both manoeuvres suggests that temporal deadspace (related to the phasic variations in ventilation and perfusion during controlled ventilation, and which one would anticipate to be increased during prolonged expiration manoeuvres) was less important than spatial, between- and within-units mismatching.[16] However, inter-individual differences in temporal ventilation–perfusion mismatching during the manoeuvres may have contributed to their poor reliability.

In summary, we have confirmed that prolonged expiration manoeuvres reduced the mean arterial to peak expired carbon dioxide partial pressure difference. However, the end-expiratory $PCO_2$ obtained with each manoeuvre agreed poorly with $Pa_{CO_2}$. This suggests that these manoeuvres should no longer be recommended to improve estimation of $Pa_{CO_2}$ from $PE'_{CO_2}$ during anaesthesia.

# Inositol 1,4,5-trisphosphate in blood and skeletal muscle in human malignant hyperthermia†

F. Wappler, J. Scholz, A. Köchling, M. Steinfath, T. Krause and J. Schulte am Esch

**Summary**

The *in vitro* contracture test (IVCT) is the only available diagnostic method at present for evaluation of malignant hyperthermia (MH) susceptibility. However, the disadvantage of the IVCT is that it is invasive. Several studies suggest that an altered inositol phosphate system is involved in the development of MH. A greater concentration of inositol 1,4,5-trisphosphate (1,4,5-IP$_3$) was found in MH susceptible (MHS) than in normal (MHN) skeletal muscles. In this study the concentrations of 1,4,5-IP$_3$ in blood samples and skeletal muscle specimens of identical patients were measured in an attempt to define susceptibility to MH. Muscle biopsies were obtained from 34 patients with clinical suspicion of MH. Patients were first classified as MHS ($n$=19), MHN ($n$=8) or MH equivocal (MHE; $n$=7) by the standard IVCT. For detection of 1,4,5-IP$_3$ concentrations, blood samples were obtained and an additional muscle specimen was excised. After sample preparation, concentrations of 1,4,5-IP$_3$ were measured using radioimmunoassay. In blood samples, concentrations of 1,4,5-IP$_3$ were similar in all individuals tested for MH susceptibility and in control patients not tested for MH susceptibility ($n$=44). In skeletal muscle, 1,4,5-IP$_3$ concentrations were significantly higher in MHS than in MHE or MHN patients, respectively. Each MHS sample contained more 1,4,5-IP$_3$ than the highest concentration measured in MHN muscle. Defining arbitrary thresholds for 1,4,5-IP$_3$ concentration in skeletal muscles in order to discriminate between MHS and MHN status, it was possible to assign three MHE patients to MHS and four to MHN. This study supports the hypothesis that an altered inositol phosphate system might be involved in MH. However, measurement of 1,4,5-IP$_3$ concentration in a simple blood sample preparation is not reliable for MH susceptibility screening. (*Br. J. Anaesth.* 1997; **78**: 541–547).

**Key words**
Anaesthetics volatile, halothane. Malignant hyperthermia Metabolism, inositol phosphate. Muscle skeletal. Screening.

Susceptibility to malignant hyperthermia (MH) in humans is diagnosed by *in vitro* contracture tests (IVCT) using halothane and caffeine on skeletal muscle specimens obtained at open biopsy.[1 2] In 1970 caffeine was introduced as the test drug for MH susceptibility followed by halothane 1 yr later.[3 4] Both caffeine and halothane produce abnormal contracture responses in muscle specimens obtained from MH susceptible (MHS) but not from normal (MHN) individuals. At present, the IVCT using caffeine and halothane is generally accepted as the "gold standard" for diagnosis of MH susceptibility. However, the major disadvantage of the IVCT is that it is invasive. Therefore, it would be desirable to have an accurate, non-invasive, low-cost screening test for MH susceptibility.

Skeletal muscle cells from MHS individuals have an inherited abnormality in the processes that are involved in the excitation–contraction coupling or myoplasmic calcium regulation,[5 6] leading to a rapid and sustained increase in myoplasmic calcium during anaesthetic-induced MH crisis. Intracellular calcium concentrations are controlled by different types of calcium release channels, that is the ryanodine receptor in the terminal cisternae of the sarcoplasmic reticulum (SR), the dihydropyridine receptor in the transverse tubule and the inositol-1,4,5-trisphosphate receptor.[6 7] In pigs, the defect predisposing to MH susceptibility is associated with the ryanodine receptor, possibly because of a specific breeding effect,[8 9] whereas the detailed molecular mechanisms leading to the human MH syndrome are still unknown. Recent studies indicated that a second factor or modulator is required for expression of the MH syndrome in humans.[10] Furthermore, dysfunction in the phosphoinositide pathway and metabolism of free fatty acids have been proposed as underlying causes of the alterations in calcium regulation in MH.[11–13] The second messenger inositol-1,4,5-trisphosphate (1,4,5-IP$_3$) has a key role in controlling both mobilization of calcium from internal stores and entry of external calcium.[14] As increased concentrations of 1,4,5-IP$_3$ were found in

MHS individuals[12] and also in MHS swine,[11] there is an increasing number of reports indicating that an altered inositol phosphate system is involved in the development of MH.[15–18] However, in skeletal muscle the sensitivity of the intracellular $Ca^{2+}$ release mechanism to 1,4,5-$IP_3$ is highly dependent on experimental conditions, and this had led to conflicting views on the role of the phosphoinositide pathway in muscle.[19]

In this study we have measured basal concentrations of 1,4,5-$IP_3$ in blood samples and skeletal muscle specimens to determine if 1,4,5-$IP_3$ concentration in blood samples from patients with clinical suspicion of MH might be a reliable non-invasive screening test for MH classification. The second aim of this study was to see if a combination of a ryanodine contracture test and measurement of 1,4,5-$IP_3$ concentrations in skeletal muscle specimens could be helpful in assigning MHE patients to MHS and MHN groups.

## Patients and methods

The study was approved by the local Ethics Committee and written informed consent was obtained from patients and their parents, if appropriate. We studied 34 patients from 19 families, 23 adults and 11 children, aged 7–44 yr, with a clinical suspicion of MH. Before starting the investigation, a personal and family history was obtained from all patients. Before operation, blood samples for measurement of 1,4,5-$IP_3$ concentration were obtained from all patients, and also from 44 control subjects without a history of MH.

### MUSCLE BIOPSIES

Adult muscle biopsies were obtained under regional anaesthesia (3-in-1 nerve block) with 1% prilocaine 40 ml. Biopsies in children were excised under general anaesthesia. Patients received midazolam 0.1 mg $kg^{-1}$ orally, 2 h before induction of anaesthesia. Anaesthesia was induced with alfentanil 50 $\mu g\ kg^{-1}$ i.v. followed by propofol 2–2.5 mg $kg^{-1}$. Before laryngoscopy and tracheal intubation, vecuronium 0.1 mg $kg^{-1}$ was given i.v. A continuous infusion of propofol $\geq 150\ \mu g\ kg^{-1}\ min^{-1}$ and 66% nitrous oxide in oxygen was used for maintenance of anaesthesia. Two or three muscle bundles were excised carefully from the vastus lateralis. The fresh specimens were placed in a container filled with carboxygenated Krebs–Ringer solution of the following composition (mmol $litre^{-1}$): NaCl 118.1; KCl 3.4; $CaCl_2$ 2.5; $MgSO_4$ 0.8; $KH_2PO_4$ 1.2; $NaHCO_3$ 25.0; and glucose 11.1, and transported to our laboratory. Apart from these specimens, an additional muscle sample (weight 200–400 mg) was excised for measurement of 1,4,5-$IP_3$ concentration. Before cutting the fibres, the muscle specimen was clamped, and immediately after excision the samples were frozen in liquid nitrogen and stored at −80 °C.

### *IN VITRO* CONTRACTURE TEST

The muscle bundles were dissected into 6–8 strips (length 15–25 mm; width 2–3 mm; weight 100–250 mg). All tests were performed within 5 h after biopsy. The muscle strips were suspended in an 80-ml organ bath perfused with Krebs–Ringer solution bubbled with carbogen continuously, temperature was kept constant at 37 °C and pH was adjusted to 7.4. Isometric tension was amplified by a Gould THE (Cleveland, OH, USA) and recorded on a Gould polygraph TA 2000 (Cleveland, OH, USA) using a Fleck TF 3V force displacement transducer (Mainz, Germany). The muscles were stimulated electrically to achieve a supramaximal response by a Grass Stimulator SD 9 (Quincy, MA, USA) using a square wave with a duration of 1 ms and a frequency of 0.2 Hz. An initial baseline tension of 20 mN was applied. Two specimens were investigated simultaneously.

Patients were classified first as MHS, MHN or MHE (MH equivocal) by the IVCT with caffeine and halothane, according to the procedure of the European Malignant Hyperthermia Group (EMHG).[1] The IVCT gave halothane and caffeine thresholds for each patient as follows: MHS=muscle contractures ≥2 mN (corresponding to ≥0.2 g in the original version of the procedure) at a caffeine concentration of 2.0 mmol $litre^{-1}$ or less *and* at a halothane threshold concentration of 0.44 mmol $litre^{-1}$ or less; MHN=muscle contractures ≥2 mN at a caffeine concentration of 3.0 mmol $litre^{-1}$ or more *and* at a halothane threshold concentration greater than 0.44 mmol $litre^{-1}$; MHE=patients with an abnormal contracture response either to caffeine (MHEc) or halothane (MHEh).

### ANALYSIS OF INOSITOL 1,4,5-TRISPHOSPHATE CONCENTRATIONS

Frozen muscle samples were powdered in a liquid nitrogen cooled dismembranator (Braun Melsungen, Germany) and the wet weight of the samples was measured. Subsequently, muscle and blood samples were mixed with 0.2 volume ice-cold 20% perchloric acid and kept on ice for 20 min. Proteins were sedimented by centrifugation at 2000 *g* for 15 min at 4 °C. Supernatants were adjusted to a pH of 7.5 by addition of 10 N KOH and kept ice-cold. Precipitated $KClO_4$ was sedimented and removed by centrifugation. Samples were neutralized by adding 300 µl of a 1:1 (v/v) of Freon (1,1,2-trichlorotrifluoroethane) and tri-n-octylamine, followed by vigorous mixing of the separate phases on a vortex mixer. After centrifugation for 1 min at 2000 *g*, three phases were obtained. A 400-µl portion of the upper phase, which contained the neutralized sample, was removed for subsequent analysis. After addition of the assay buffer (D-myo-[$^3H$] inositol-1,4,5-trisphosphate) and 1,4,5-$IP_3$ binding protein, samples were incubated for 15 min and centrifuged. After decanting and discarding the supernatant, the pellets were resuspended and 2 ml of scintillant added to each tube. Subsequently, radioactivity was measured in a β-scintillation counter. For calculation of the results a standard curve, generated by plotting the percent $B/B_0$ as a function of $\log_{10}$ 1,4,5-$IP_3$ concentration was used.

RYANODINE CONTRACTURE TEST

After the IVCT, surplus muscle specimens were used in the ryanodine contracture test for diagnosis of MH susceptibility, as described recently.[20] Ryanodine was added as a bolus to the organ bath in order to obtain a concentration of 2 μmol $litre^{-1}$. The development of contracture after ryanodine administration was characterized by attainment of three phases: (1) start of contracture (min); (2) time (min) when contracture reached 2 mN; and (3) time (min) when contracture reached 10 mN. With the results for MHS and MHN after ryanodine 2 μmol $litre^{-1}$, we arbitrarily defined time intervals to assign MHE patients to either the MHS or MHN group, respectively.

The following chemicals were used: caffeine (Sigma, Deisenhofen, Germany), halothane (Hoechst, Frankfurt, Germany), ryanodine (purity >99% by HPLC; Calbiochem, La Jolla, USA). All substances were prepared freshly, dissolved in pre-warmed and pre-gassed Krebs–Ringer solution at 37°C and added directly to the organ bath. Halothane was added to carbogen from a Dräger vaporizer (Lübeck, Germany); the concentration of halothane was measured with an anaesthetic gas monitor (Normac, Datex, Helsinki, Finland). Bath concentration of halothane was measured by gas chromatography.[21]

STATISTICAL ANALYSIS

Data are presented as median, range and SD (patients characteristics). Values were analysed using the Kruskal–Wallis and Mann–Whitney non-parametric tests to determine differences between groups. Results were considered significant if $P<0.05$.

## Results

Nineteen patients were classified as MHS, eight as MHN and seven as MHE, according to the IVCT criteria of the European MH Group. Patient characteristics did not differ significantly (see table 1), but because one MHE patient had a creatine kinase (CK) concentration of 1800 iu $litre^{-1}$, CK values at rest were significantly greater in the MHE (315.7 (615.5) iu $litre^{-1}$) than in the MHS (61.6 (28.3) iu $litre^{-1}$) and MHN (55.6 (27.1) iu $litre^{-1}$) groups.

In simple blood sample preparations, 1,4,5-$IP_3$ concentrations were similar in all individuals tested for MH susceptibility and in control patients (fig. 1). Concentrations of 1,4,5-$IP_3$ in the MHS group ranged from 4.3 to 11.6 (median 8.7) pmol/tube. In the MHE group, values were 5.1–12.5 (median 9.9) pmol/tube. Median 1,4,5-$IP_3$ concentrations in the MHN group (5.5 pmol/tube) were smaller than those in the other groups. However, the range (4.0–11.0 pmol/tube) did not differ significantly from concentrations in the MHS and MHE groups. The control population showed a homogeneous distribution with a minimum of 3.4 and a maximum of 12.0 pmol/tube, which were similar to the results of the MH patients.

In skeletal muscles from the same patients, there were significant differences in 1,4,5-$IP_3$ concentrations (fig. 2). The median in the MHS group (6.2 pmol/mg ww) was significantly higher than that in the MHN group (1.7 pmol/mg ww). The ranges in both groups also showed marked differences: 1,4,5 $IP_3$-concentrations in the MHN group were 0.2–2.8 pmol/mg ww compared with 2.9–12.8 pmol/mg ww in the MHS group. Concentrations of 1,4,5-$IP_3$ in MHE individuals were between those of the MHS and MHN subjects, and were significantly different

from the MHS results. Individual data for three MHE patients varied from 3.7 to 7.0 pmol/mg ww, corresponding to the range of values for MHS, and four values varied from 0.5 to 2.0 pmol/mg ww, corresponding to MHN.

Individual data for contracture testing using ryanodine 2 $\mu$mol litre$^{-1}$ are presented in table 2. Contracture development after ryanodine administration was enhanced significantly in MHS compared with MHN muscles. Median values for MHE muscles were always between those of MHS and MHN.

Table 3 summarizes the results of the IVCT, 1,4,5-IP$_3$ concentrations in skeletal muscle and the ryanodine contracture test in MHE patients. In an attempt to assign MHE muscles to either the MHS or MHN group, we arbitrarily defined thresholds for 1,4,5-IP$_3$ concentrations in skeletal muscles of $\geq$2.9 pmol/mg ww for MHS and $\leq$2.8 pmol/mg ww for MHN. Thus an assignment of three MHE patients to the MHS group was possible. MHE patient Nos 1, 3, 6 and 7 were defined as MHN. Using the range of values for MHS and MHN according to the ryanodine contracture test, we arbitrarily defined intervals to categorize MHE muscles as either MHS or MHN, as described recently.[20] Three MHE muscles showed enhanced contracture development and were classified as MHS. In four muscles a marked delay in contracture development occurred and these were allocated to the MHN group. In five

*Table 3* Results of *in vitro* contracture tests with halothane and caffeine (IVCT), measurement of inositol 1,4,5-trisphosphate (1,4,5-IP$_3$) concentration in skeletal muscles and the ryanodine contracture test (RCT) using ryanodine at a concentration of 2 $\mu$mol litre$^{-1}$ in malignant hyperthermia equivocal (MHE) patients

| Patients No. | IVCT | 1,4,5-IP3 (pmol/mg ww) | RCT |
|---|---|---|---|
| 1 | MHE | MHN (0.5) | MHS |
| 2 | MHE | MHS (4.1) | MHN |
| 3 | MHE | MHN (2.0) | MHN |

| 6 | MHE | MHN (1.2) | MHN |
| 7 | MHE | MHN (1.9) | MHN |

of seven MHE muscles, consistent results in both tests were observed. The same MH classification was possible using measurement of 1,4,5-$IP_3$ concentrations and ryanodine contracture testing.

## Discussion

We have found that 1,4,5-$IP_3$ concentrations in skeletal muscle specimens were significantly higher in MHS than in MHN patients. In contrast, 1,4,5-$IP_3$ concentrations in blood samples of the same patients and controls did not differ. Thus it was possible to differentiate between MHS and MHN individuals by measurement of 1,4,5-$IP_3$ concentrations in skeletal muscle specimens but not in simple blood sample preparations. Furthermore, we have demonstrated that a combination of a ryanodine contracture test and measurement of 1,4,5-$IP_3$ concentrations in skeletal muscle specimens could be helpful in assigning MHE patients to MHS and MHN groups.

For evaluation of susceptibility to MH, only the *in vitro* contracture tests with halothane and caffeine have been shown to be reliable in distinguishing between MHS and MHN individuals. Human skeletal muscle contracture testing for diagnosis of MH susceptibility seems to be highly sensitive.[22] However, the specificity of the IVCT was estimated as 80–85%.[23] For the first time in 1993 four cases were described of presumably false-negative contracture responses in muscle specimens from patients with a clinical history of MH.[24] However, there is considerable debate about these cases because the authors did not use the EMHG test procedure; in two cases there was no clinical evidence of MH and muscle histology and neurological examination were not performed in all patients. Four additional cases were presented recently of false-negative IVCT results in juvenile patients surviving MH episodes during general anaesthesia.[25] The authors suggested that the age of the patients might have affected the contracture results. However, whereas in newborn MHS piglets decreased responsiveness to halothane compared with mature animals has been observed,[26] age dependence of MH in humans has not been demonstrated until now.

The caffeine contracture test produces false-negative results in approximately 15% of MH susceptible patients. Moreover, both caffeine and the halothane tests were shown not to be specific for MH, as positive IVCT results were observed in some individuals with other muscle disorders.[27] Contracture test results in control patients suggested a false-positive rate of approximately 4% using the European[28] and 9% using the North American MH procedures.[23] The hypothesis that MH is caused by an abnormal ryanodine receptor gene focused interest on developing an alternative test for diagnosis of MH using ryanodine. *In vitro* studies of ryanodine-induced contractures showed that in muscle specimens of MHS patients, contractures developed significantly earlier than in specimens from MHN individuals.[20 29–32] Although the results of contracture testing with ryanodine in conjunction with the standard halothane and caffeine contracture tests could improve diagnosis of MH susceptibility,[33] the ryanodine contracture test is also not specific for MH. Moreover, the disadvantage of contracture testing with halothane, caffeine and ryanodine is that it is invasive, time consuming and expensive.

Since the identification of the ryanodine receptor gene, thought to be responsible for MH,[34 35] it has been assumed that MH susceptibility could be detected using a genetic test based on DNA analysis. Molecular genetic studies have shown that a single point mutation in the ryanodine receptor gene (C1843-T mutation) is frequently correlated with MH in swine.[9] However, the corresponding mutation in the human genom (C1840-T mutation) was detected first in only one of 35 MH families.[36] At present, the frequency of this single point mutation in the human ryanodine receptor gene has been calculated to be less than 10%.[10 37] Moreover, mutation screening of the ryanodine receptor gene in MHS individuals has led to the identification of seven other mutations to date.[38] Furthermore, genetic heterogeneity has been reported in MH[39] and several additional MHS loci on chromosomes 17, 7 and 3.[40–42] DNA-based testing in MH would be non-invasive, accurate and less expensive, but there is little probability that a universal genetic test for MH susceptibility in humans will be easily developed because of heterogeneity, increasing number of identified mutations in MH and association with muscle cell deficiencies induced by other neuromuscular diseases.

Activation of G protein-linked receptors led to the dissociation of the G protein in the subunits $G_\alpha$ and $G_{\beta\gamma}$, both of which can activate different phospholipase C (PLC) enzymes.[14] In energy-requiring transducing mechanisms, PLC hydrolyses the lipid precursor phosphatidylinositol 4,5-bisphosphate to stimulate formation of both diacylglycerol (DAG) and 1,4,5-$IP_3$, which binds to an 1,4,5-$IP_3$ receptor to mobilize stored $Ca^{2+}$. It is believed that abnormal regulation of intracellular $Ca^{2+}$ concentration within skeletal muscle is the process of primary significance in MH episodes. Furthermore, malfunctions in the phosphoinositide cycle and free fatty acid metabolism were shown to be associated with MH susceptible muscle.[11–13 16–18] Basal concentrations of 1,4,5-$IP_3$ in skeletal muscles of MHS swine[11] and humans[12] were found to be significantly higher than in MHN. It was demonstrated that successive additions of 1,4,5-$IP_3$ induced short pulses of calcium release.[43] Moreover, microinjection of 1,4,5-$IP_3$ increased intracellular $Ca^{2+}$ in intact skeletal muscle from MHS swine with higher potency and efficacy than in muscles from MHN swine.[15] Dantrolene decreased resting intracellular $Ca^{2+}$ concentration and prevented 1,4,5-$IP_3$-induced increase in intracellular $Ca^{2+}$. These results suggest that skeletal muscle fibres from MHS have a higher sensitivity to 1,4,5-$IP_3$-induced regulation of intracellular $Ca^{2+}$, which could play an important role in MH induction. In the presence of halothane, 1,4,5-$IP_3$-concentration increased to a higher extent in MHS than in MHN muscles.[11] Moreover, it has been shown that halothane challenge caused an increase in the second messengers 1,4,5-$IP_3$ and 1,3,4,5-$IP_4$ in MHS but not in MHN swine.[18] Treatment with dantrolene reduced the increase to values close to basal concentrations. To date, it is not clear if the alterations in phosphoinositide metabolism are primary in MH induction or of a secondary nature. ATP at low concentrations enhances the ability of 1,4,5-$IP_3$ to open $Ca^{2+}$ channels in the SR membrane. It has been hypothesized that the lower the ATP concentration, possibly as a result of the hypermetabolic state of MH, and the higher the 1,4,5-$IP_3$ concentration, the more $Ca^{2+}$ is released.[17] It has been speculated therefore that measurement of $Ca^{2+}$ or 1,4,5-$IP_3$ concentrations, or both, in muscle but also in non-muscle cells, could be used for diagnosing MH susceptibility.[44–46] However, the differences in these investigations were not reliable in determining susceptibility to MH until now.[46] Moreover, in accordance with our data from simple blood sample preparations, no differences in 1,4,5-$IP_3$ concentrations in human red blood cells were observed between MHS and MHN.[47]

In summary, this study supports the hypothesis that an altered inositol phosphate system might be involved in MH. One might speculate that the differences between skeletal muscles might also exist in other cell types, including blood cells. Further investigations are required to develop an accurate, reliable, low-cost and non-invasive screening test. Such a test might be measurement of 1,4,5-$IP_3$ concentration in different blood components or cell types, or methods of detecting genetic defects in 1,4,5-$IP_3$ metabolism.

LABORATORY INVESTIGATIONS

# Leucocyte-derived bioactive substances in fresh frozen plasma

H. J. NIELSEN, C. REIMERT, A. N. PEDERSEN, E. DYBKJŒR, N. BRÜNNER, B. ALSBJØRN AND P. STAHL SKOV

## Summary

Bioactive substances in fresh frozen plasma (FFP) are considered to be related to adverse reactions after transfusion, particularly in septic or traumatized patients. Therefore, we analysed the concentration of various bioactive substances (histamine, eosinophil cationic protein, eosinophil protein X, myeloperoxidase and interleukin-6) in 25 u. of thawed FFP from healthy donors. These were compared with donor plasma concentrations of 24 healthy controls. In addition, we analysed the concentration of the bioactive substances, except interleukin-6, in 25 u. of thawed FFP, which were subjected to leucocyte filtration before freezing and storage. Finally, we analysed the substances in 10 leucocyte non-filtered plasma units before freezing and storage, and after thawing, respectively. Before analyses, which were performed by ELISA and RIA methods, these latter samples were sterile filtered through a 0.20-μm filter. Histamine, eosinophil cationic protein, eosinophil protein X and myeloperoxidase concentrations were significantly greater ($P<0.05$) in the 25 u. of FFP compared with normal donor plasma. Pre-storage leucocyte filtration reduced concentrations of the bioactive substances in FFP to concentrations comparable with normal donor plasma concentrations. Interleukin-6 was undetectable in all FFP units and in 21 of the 24 control donors. Histamine, eosinophil cationic protein and myeloperoxidase concentrations were significantly higher ($P<0.05$) in samples collected from the 10 u. of FFP after freezing and thawing compared with samples collected before freezing. We conclude that fresh frozen plasma prepared by a conventional separation method contains various leucocyte-derived bioactive substances, which may be reduced by pre-storage leucocyte filtration. (*Br. J. Anaesth.* 1997; **78**: 548–552).

**Key words**
Blood, fresh frozen plasma. Blood, transfusion. Blood, leucocytes. Immune response.

Blood transfusion therapy has changed from whole-blood products towards component therapy, and plasma preparations are at present a valuable component in massive transfusion regimens. The interest in transfusion-induced detrimental effects has focused primarily on leucocyte-containing blood products.[1 2] Evidence has emerged, however, suggesting that plasma and plasma derivatives contribute to adverse reactions in transfusion therapy.[3 4] The mechanisms of plasma component-induced adverse effects are largely unknown, but plasma proteins, alloantigens, alloantibodies and undefined bioactive substances, particularly in fresh frozen plasma (FFP), may participate in post-transfusion adverse reactions.[3 4] Thus FFP may play a role in transfusion-related acute lung injury (TRALI),[5] adult respiratory distress syndrome (ARDS),[6] febrile non-haemolytic transfusion reaction (FNHTR),[3 4] fatal shock in septicaemia[7] and possibly in immunosuppression.[8]

Previously, we showed time-dependent cumulation of histamine, eosinophil cationic protein (ECP), eosinophil protein X (EPX), myeloperoxidase (MPO) and plasminogen activator inhibitor-1 (PAI-1) from basophils, eosinophils, neutrophils and platelets, respectively, in supernatants from various erythrocyte suspensions during storage.[9 10] Fresh plasma contains approximately $5\times10^5$ leucocytes per unit, while leucocytes are undetectable in FFP thawed before clinical use.[3] This suggests that leucocytes contaminating FFP are totally lysed and therefore may have released their preformed bioactive substances contained within intracellular granules.

The purpose of this study was to evaluate concentrations of various leucocyte- and platelet-derived bioactive substances in FFP. In addition, we studied the effect of pre-storage leucocyte filtration on concentrations of bioactive substances.

## Subjects and methods

Peripheral venous blood (4.5 ml) was obtained from 24 randomly selected normal donors to establish

normal plasma concentrations of histamine, ECP, EPX, MPO, PAI-1 and interleukin-6 (IL-6). Blood was obtained into ice-chilled endotoxin-free glass tubes (Beckon-Dickinson, Mountain View, CA, USA) containing 0.5 ml of sodium citrate 0.129 mol $\text{litre}^{-1}$ and aprotinin 12.5 kiu $\text{ml}^{-1}$. Sodium citrate was used as an anticoagulant because of the recent finding of contamination of heparin preparations by histamine,[11] and because sodium citrate is used in standard blood bags (Baxter SA, La Chatre, France) at our institution. Subsequently, blood was centrifuged at +4 °C at 1200 *g* for 10 min. Plasma was separated carefully from cells and frozen at −70 °C.

FFP was prepared from 450 ml of blood donated into blood bags (Baxter SA) containing 63 ml of citrate, phosphate and dextrose solution (CPD) as anticoagulant. Within 1 h after donation, fresh plasma was separated from red cells and buffy-coat by centrifugation of the blood bag at 5000 *g* for 8 min, followed by transfer of plasma to a separate bag containing 280±10 ml of plasma. Finally, plasma was quick-frozen in absolute alcohol at −39.4 °C and stored at −25 °C until use. In addition, 25 other units of plasma prepared from whole blood by a similar procedure were subjected to leucocyte filtration before freezing and storage, using the LPS2E leucocyte filter (Pall Biomedicals Ltd, Portsmouth, UK). The filter was connected between the plasma bag and the empty bag by using a sterile welding technique.

We obtained samples (5.0 ml in endotoxin-free plastic tubes, Beckon-Dickinson) from 25 u. of leucocyte non-filtered and 25 u. of leucocyte-filtered FFP, respectively, before transfusion to burn trauma patients. The samples were collected after FFP had been thawed in a water bath at +37 °C for 30 min, kept on ice, and subsequently frozen at −70 °C until analysis.

Samples were also collected from 10 additional plasma units before freezing. These samples (5.0 ml) were centrifuged at +4 °C at 5000 *g* for 15 min and only the top 80% of the plasma of each tube was collected for analyses. Thereby, the bottom 20% of the plasma, which may contain cellular debris, was not used for analyses. To assure complete absence of free leucocyte granules in samples for analyses, plasma was sterile-filtered using a 0.20-μm filter (Sterile AerodiscR, Gelman Sciences Inc., Ann Arbor, MI, USA). Subsequently, the 10 u. of plasma were frozen and thawed as described previously, and the sample, centrifugation, separation and sterile filtration procedures were repeated.

When all samples were collected, normal plasma and FFP concentrations of histamine were analysed using a commercially available ELISA method (Immunotech SA, Marseilles, France) as described previously[9] (detection limit=0.5 nmol $\text{litre}^{-1}$). ECP and EPX were analysed using ELISA methods[12,13] (detection limits=15 pg $\text{ml}^{-1}$ and 60 pg $\text{ml}^{-1}$, respectively). MPO and IL-6 were analysed using commercially available RIA (MPO RIA, Pharmacia AB, Uppsala, Sweden) and ELISA (IL-6, Immunotech SA, Marseilles, France) methods (detection limits=8 ng $\text{ml}^{-1}$ and 3.9 pg $\text{ml}^{-1}$, respectively). In addition, PAI-1 from platelets was analysed in supernatants from the 10 u. of FFP before freezing and after thawing to detect eventual platelet contamination of FFP. PAI-1 was analysed by an ELISA method[14] with a detection limit of 20 pg $\text{ml}^{-1}$. All analyses were performed in duplicate.

Differences between normal donor plasma concentrations and FFP concentrations before transfusion, and differences in concentrations in plasma samples before and after freezing–thawing were evaluated statistically using the Mann–Whitney test. All values are given as median (range). $P<0.05$ was considered significant.

## Results

Median donor plasma concentrations of histamine, ECP, EPX, MPO and IL-6 are shown in table 1. Plasma concentrations of IL-6 were below the detection limit (3.9 pg $\text{ml}^{-1}$) in 21 of the 24 control donors.

Concentrations of histamine, ECP, EPX, MPO and IL-6 in leucocyte non-filtered FFP and histamine, ECP, EPX and MPO concentrations in leucocyte-filtered FFP are also shown in table 1. Histamine ($P<0.05$), ECP ($P<0.05$), EPX ($P<0.05$) and MPO ($P<0.01$) concentrations were significantly higher in leucocyte non-filtered FFP compared with donor plasma concentrations and with concentrations in leucocyte-filtered FFP. Interleukin-6 was not analysed in leucocyte-filtered FFP because it was undetectable in non-filtered FFP.

Donor blood for analysis of plasma bioactive substance concentrations was diluted 1:10 by sampling 4.5 ml of blood in 0.5 ml of sodium citrate and aprotinin. Thereby, control donor plasma concentrations may be diluted by 1:6.4 when using an average packed cell volume of 0.4. Similarly, donor blood (450 ml) was diluted by 63 ml of CPD in the bags, and when using a mean packed cell volume of 0.4, the substance concentration in FFP may be

*Table 1* Donor plasma and fresh frozen plasma (FFP) concentrations of various bioactive substances (median (range)). $^{*}P<0.05$ *vs* donor plasma and leucocyte-filtered FFP; $^{**}P<0.01$ *vs* donor plasma and leucocyte-filtered FFP. nd=Not determined

diluted by 1:5.3. Therefore, the concentrations of histamine, ECP, EPX and MPO detected in FFP may be slightly underestimated compared with donor plasma concentrations.

Concentrations of histamine, ECP, EPX, MPO, PAI-1 and IL-6 in the repeated samples of the 10 u. of fresh plasma and frozen–thawed plasma are shown in table 2. Histamine ($P<0.05$), ECP ($P<0.05$) and MPO ($P<0.01$) concentrations were significantly higher after freezing and thawing compared with fresh plasma before freezing. EPX concentrations were only slightly increased, and PAI-1 concentrations were reduced in all analyses compared with donor plasma concentrations, which in the 24 normal donors were 8.9 (2.6–34.7) ng ml$^{-1}$. IL-6 could not be detected in these samples.

## Discussion

Despite careful donor selection and extensive testing, transfusion of allogenic blood products is associated with adverse reactions, such as immunomodulation,[2] TRALI,[5] ARDS,[6] FNHTR,[3 4] graft-*vs*-host disease (GVHD)[15] and, rarely, transmission of infectious agents.[16] Furthermore, perioperative transfusion with allogenic blood may induce immunosuppression[17 18] which subsequently may increase the risk of developing postoperative infectious complications[2] and increase the risk of recurrence after curative cancer surgery.[2] Hitherto, the mechanisms of these blood transfusion-induced adverse reactions have been poorly understood, but human leucocyte antigen (HLA) expression on donor leucocytes[3] has been suspected to play a role. Consequently, the use of autologous blood has increased, particularly in elective surgery,[19] and it was anticipated to have beneficial effects on blood transfusion-induced infectious complications and on long-term survival. However, results from studies in cancer surgery comparing the effect of allogenic and preoperative donated autologous blood have shown a similar, higher cancer recurrence rate[20] and reduced long-term survival rate[21] in both transfused groups compared with non-transfused patients. Therefore, it was hypothesized that bioactive substances released into the non-cellular component of various transfusion products may play a common role in transfusion-induced adverse effects.[2]

Results from recent studies suggest storage time of blood products plays an important role in the development of adverse reactions[22–24] induced by cytokines[25] and substances with mitogenic activity[22] released into the supernatant. We previously showed storage time-dependent release of histamine, ECP, EPX, MPO and PAI-1 in various erythrocyte suspensions which contain leucocytes and platelets[9 10] while IL-6 was undetectable[10] during storage at +4 °C for 35 days. Results from this study showed that leucocyte non-filtered FFP contained significant amounts of histamine, ECP, EPX and MPO, while IL-6 was not increased compared with control donor plasma concentrations (table 1). In addition, increased concentrations of histamine, ECP and MPO in the 10 u. of thawed FFP compared with samples collected before freezing (table 2) indicated that the substances were released from leucocytes, which are retained in various amounts in plasma during blood component preparation. This assumption is supported by the reduced concentrations of the bioactive substances in pre-storage leucocyte-filtered FFP (table 1). Furthermore, by using sterile microfiltration of plasma from the 10 u. of FFP (table 2) we may have avoided the influence of cellular debris on the analysis of the results. In addition, the low PAI-1 concentration in FFP (table 2) suggests that platelets were retained in the buffy-coat during blood component preparation.

Histamine, ECP, EPX and MPO are preformed and contained in granules in basophils, eosinophils and neutrophils, respectively, while IL-6 is synthesized and released after stimulation[26] and not contained in preformed granules. The freeze–thawing technique used for preparation of FFP at transfusion may lead to total lysis of leucocytes, and simultaneous release of their many bioactive substances into plasma.[9 10] This is supported by detection of leucocytes in fresh plasma[3] while leucocytes are undetectable in thawed FFP.[3]

The clinical impact of these findings is not clear, but as FFP units contain approximately 280 ml of plasma in CPD, the amount of transfused bioactive substances may be significant, at least in massive transfusions, for example to burn trauma patients[27] where accumulation of bioactive substances was related to post-trauma septic reactions.[27] This supports experimental results showing that repeated plasma transfusions are fatal in septicaemic animals.[7] Considerable evidence has emerged to suggest that histamine may have beneficial and detrimental effects on the inflammatory response, immune reaction, coagulation cascade and cardiovascular function.[28–30] ECP and EPX may contribute to immunomodulation, tissue damage and neurotoxicity,[31–34] while MPO may amplify toxic reactions and oxygen free radical-induced tissue damage by hypochlorous acid (HOCl) and N-chloramine (RNHCl) generation.[35–39] Furthermore, some of the substances transfused via FFP are suspected to induce further release of similar and other bioactive substances in the recipient.[40–42] This may support the assumption that bioactive substances in FFP and in other blood products may be detrimental for patients with trauma, septicaemia or undergoing major operations for burn trauma or cardiopulmonary bypass.[2 7 9 43–45]

Although the well known adverse effects of blood component transfusion have been attributed primarily to the presence of contaminating leucocytes, recent data and our data suggest that bioactive substances contained in intracellular granules of leucocytes may play an additional role. Therefore, it should be considered that substances which normally are synthesized and released to protect the host against alloantigen exposure[29 30] occasionally may be detrimental when transfused as part of a massive transfusion regimen. Pre-storage leucocyte filtration should be considered to reduce the content of bioactive substances in FFP, and thereby possibly improve outcome in recipients. The clinical effect of component therapy with exclusively pre-storage leucocyte-filtered blood products compared with conventional prepared products are currently being evaluated in a randomized study of burn trauma patients.

# Responses to simulated anaesthetic emergencies by anaesthetists with different durations of clinical experience

A. J. BYRNE AND J. G. JONES

## Summary

We have compared the responses of four groups of anaesthetists, with different durations of clinical experience, to nine different simulated emergencies. Five anaesthetists in each group completed each of the nine simulated emergencies. Anaesthetists with less than 1 yr experience performed less well than the three other groups of anaesthetists (chi-square, $P<0.02$). However, all groups made serious errors in both diagnosis and treatment, and accepted treatment guidelines were not followed. We have shown that a simple, inexpensive simulator can be used to evaluate the performance of anaesthetists of different durations of clinical experience. (*Br. J. Anaesth.* 1997; **78**: 553–556).

**Key words**
Model, computer simulation. Anaesthesia, audit. Anaesthetists, training.

Errors in the management of emergency situations during anaesthesia are a continuing cause of mortality and morbidity.[1] While both anaesthetic mortality and morbidity are relatively infrequent, the cost in psychological, social and medico-legal terms is considerable. Because these complications are relatively infrequent it is difficult to train anaesthetists to deal with such complications when they occur. Consequently, there is considerable interest in the use of simulators, both in the training of anaesthetists and in the assessment of treatment guidelines.[2–7] Several groups of workers have designed simulators and have investigated their role in education and research.[8–10] While inexpensive computer-based simulators have been criticized for being unrealistic and not testing physical skills, full scale, "high fidelity" simulators, which may cost in excess of £100 000, are likely to be much too expensive to be purchased by individual departments of anaesthesia.

The Anaesthetic Computer Controlled Emergency Situation Simulator (ACCESS)[11] is a "full-scale", "intermediate-fidelity" system and was designed to provide realistic training and a method of assessing performance. Its cost (approximately £3000) is less than many individual pieces of routine anaesthetic monitoring equipment. We have used the simulator to evaluate the performance of anaesthetists with different clinical experience.

## Methods

The ACCESS system consists of a resuscitation manikin representing the patient, a real anaesthetic machine/ventilator and a personal computer which has been programmed to produce a representation of commonly used anaesthetic monitors. The simulations run in real time and are designed to test cognitive and physical skills. Nine different emergencies were presented (table 1).

The simulations were designed to test the most basic anaesthetic skills such as monitoring pulse and ventilation. In addition, the simulated emergencies required the anaesthetist to identify the problem and then to solve it in the same way as during a real emergency, that is by injecting drugs, infusing fluids or altering the settings on the anaesthetic machine.

Each scenario had a predetermined series of therapeutic actions which needed to be taken, but strict adherence to accepted treatment guidelines was not required to cure the "patient". For example, the scenario of anaphylaxis required discontinuation of the anaesthetic and administration of adrenaline and i.v. fluids in appropriate amounts.

We have compared the performance of four groups of anaesthetists with anaesthetic experience allocated to one of four groups: less than 1 yr, between 1 and 2.5 yr, between 2.5 and 5 yr and more than 5 yr. In each experience group, the results for each of five anaesthetists to manage the situation were studied, giving a total of 180 simulations.

All candidates were given a few minutes' explanation before using the simulator but were not allowed any trial runs. The tutor acted as an assistant, passing drugs and equipment, and driving the simulation, but not providing any clues as to the diagnosis or possible treatments. The actions of each anaesthetist were observed and significant actions were timed to the nearest 30 s. The "time to solve" represented the total time for the anaesthetist to identify

Correspondence to A. B.

the problem, formulate a solution and perform any necessary actions.

Each simulation was followed through to either patient "recovery" or "death". The times recorded for each scenario are not directly comparable because they represent a range of activities. For example, to cure bradycardia, a single action was required, that is giving a dose of atropine, while in the emergency involving hypotension, the volatile anaesthetic and nitrous oxide had to be discontinued and then fluid administered via the i.v. cannula in the "patient's" arm.

Within each emergency, individual times to successful completion were averaged and SD calculated. Each individual's time was then classified as being either "fast" (less than average for that emergency), "intermediate" (longer than average but not by more than two SD) or "slow" (longer than average plus two SD). Any cases of unsuccessful treatment were also classified as "slow". The statistical significance of the observed differences were assessed using the chi-square test, with Bonferroni correction where appropriate.

## Results

During the study the simulator functioned as expected and all anaesthetists were able to complete their simulations. Responses to 180 emergencies were studied. The emergencies used and the results obtained for each emergency are shown in table 1.

Inadequate treatment leading to the "death" of the "patient" occurred only in the simulation of asystole (10 of 20 simulations), oxygen supply contamination (three of 20), anaphylaxis (five of 20) and failed intubation (14 of 20).

*Table 1* Simulated emergencies, showing the number of "patients" treated inadequately and the average (SD) time to successful treatment. ($n=20$ for each emergency)

| Emergency | Inadequate treatment | Average time (s) |
|---|---|---|
| Bradycardia | 0 | 78.0 (55.6) |
| Hypotension | 0 | 186 (119) |
| Oxygen contamination | 3 | 143 (105) |
| Ventricular tachycardia | 0 | 239 (143) |
| Awareness | 0 | 153 (76.4) |
| Anaphylaxis | 5 | 236 (105) |
| Bronchospasm | 0 | 173 (90.1) |
| Failed intubation | 14 | 220 (87.7) |
| Asystole | 10 | 204 (65.0) |

*Table 2* Simulation emergencies, showing the number of anaesthetists in each group (see text for details) divided into time to treat ($n=20$ for each group)

| Emergency | Fast | Intermediate | Slow |
|---|---|---|---|
| Bradycardia | 12 | 7 | 1 |
| Hypotension | 13 | 6 | 1 |
| Oxygen contamination | 10 | 5 | 5 |
| Ventricular tachycardia | 9 | 11 | 0 |
| Awareness | 13 | 5 | 2 |
| Anaphylaxis | 8 | 6 | 6 |
| Bronchospasm | 11 | 8 | 1 |
| Failed intubation | 3 | 1 | 16 |
| Asystole | 4 | 6 | 10 |

On average, the anaesthetists identified the problem and took appropriate action within 180 s (range 30–570 s). The variation in the time between emergencies reflected both the difficulty in diagnosing the problem and the number of interventions needed to cure the "patient".

Table 2 shows the performance of the anaesthetists during each simulated emergency. As indicated previously, "fast" treatment was considered to be faster than the average for that emergency and "slow" treatment implied either slower than two SD longer than the average time or inadequate treatment.

Figure 1 shows the performance of the four groups of anaesthetists. The most inexperienced group showed fewer "fast" performances and more "slow" performances compared with the three other groups. Overall, the speed of treatment was related to the experience of the anaesthetist ($P<0.02$). When the results of the most inexperienced group were compared with the amalgamated results of the other groups, they were significantly worse ($P<0.02$ with Bonferroni correction).

Although anaesthetists with more than 1 yr experience performed better than inexperienced anaesthetists, they still made serious errors in the treatment of their "patients". For example in the simulation of failure to intubate and ventilate, all anaesthetists eventually resorted to cricothyroid puncture but only six knew how to connect the cannula to a source of oxygen and ventilate the patient's lungs. In the simulations involving cardiac

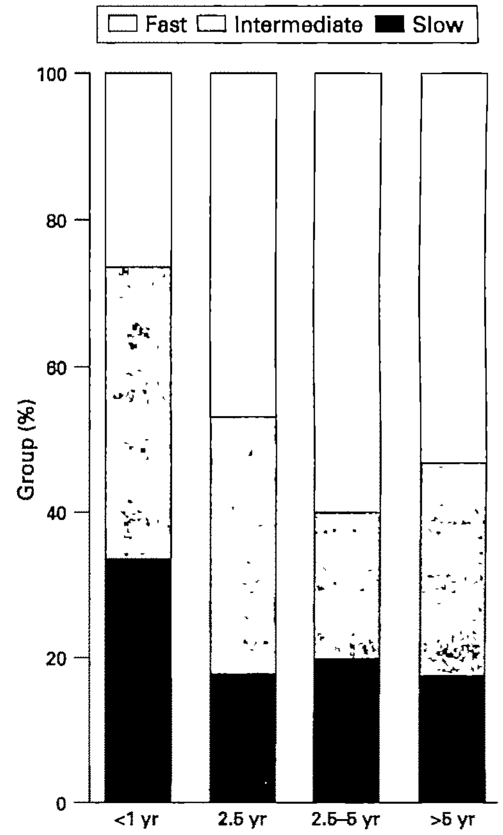

*Figure 1* Percentage of each group of anaesthetists, divided into duration of experience, in each of the three classes of performance. $n=45$ for each group.

arrest or anaphylaxis, no anaesthetist followed the relevant guidelines.

## Discussion

We have demonstrated that the ACCESS simulator can be used to assess the ability of anaesthetists to deal with anaesthetic emergencies. It was able to detect a significant difference in the performance of inexperienced (<1 yr) compared with more experienced anaesthetists. Although a relationship between performance and experience was detected, the results were worrying in that none of the groups of anaesthetists tested, regardless of the duration of training, seemed to be able to deal with all of the simulated emergencies efficiently.

This study can be criticized for not testing anaesthetists during real critical incidents involving real patients. Unfortunately, the rarity of such critical incidents, their inherent variability and their associated medico-legal problems implies that it is practically impossible to study anaesthetists' performances in real-life emergencies. Another criticism is that the simulator is not realistic enough for the results to be used to modify real anaesthetic practice. Editorials published in the anaesthetic literature as far back as 1986[2–7] have commented on the need for new training techniques in anaesthesia and one leading expert in the field has written[4]: "... no industry in which human lives depend on the skilled performance of responsible operators has waited for unequivocal proof of the benefits of simulation before embracing it. In my opinion, neither should anesthesiology". Indeed, in the aviation industry pilots may be exclusively trained and assessed on simulators, so that their first experience of flying the real aeroplane is on a scheduled flight.[12]

The crucial question is whether or not the subjects being tested were able to suspend disbelief. Thus if they are able to react to the simulated events as if they were real, for example saying "Oh no, arterial pressure is falling, can you get me some ephedrine please?", then this is good evidence that disbelief has been suspended. Under these conditions subjects use the same mental models as they use in real life and results are therefore valid.

On the issue of the complexity and realism of the simulator, only six previous articles have described the performance of those tested using time as a criterion.[9 11 13–16] One article described the results from a purely screen-based simulator,[15] while others were based on full-scale, "high fidelity" simulators. The groups included first and second year anaesthetic residents,[9] first and second year anaesthetic residents and experienced practitioners[13] and residents, attendings and anaesthetists in practice.[15]

All of these studies have shown results similar to those produced by ACCESS; performance improved with experience but performance varied greatly, both within and between individuals. When asked to assess the realism of the simulated scenarios on a linear scale of 1 to 10 (10 being totally realistic), in all published evaluations, simulators were rated as between 8 and 8.2,[8 11 17] regardless of whether they were purely computer-based or "full-scale, high fidelity" models. In keeping with the results from ACCESS, the only significant difference in performance was that between the first and second years of training.[9 13] The simplicity of the simulator does not therefore seem to impair the ability to measure performance, which is in keeping with the concept that it is not necessary to construct a "high-fidelity" environment, but merely to provide enough realism to enable those tested to suspend disbelief.

Unfortunately the use of "time to solve" a simulated emergency as a measure of performance may not reflect competence to deal with actual clinical emergencies. For example, in the simulation of bronchospasm it was only the inexperienced anaesthetists who changed the tracheal tube before giving bronchodilators. The more experienced anaesthetists always assumed that the tracheal tube was not the cause of increased airways resistance. This caused some of the less experienced anaesthetists to record a longer "time to solve", but may represent a safer approach. In addition, these results examined only the ability to deal with acute emergencies, they did not test the ability to avoid critical incidents through safe practice.

In addition, classification of anaesthetists by number of years working in anaesthesia does not necessarily take into account seniority. Some of those tested had a considerable number of years of experience, but had not progressed up the career ladder. Although the performance of those anaesthetists might have contributed to the failure of this study to demonstrate a linear relationship between performance and experience, it is important to note that "poor" performances were still recorded by consultant anaesthetists.

Data collected from critical incident studies has been used to validate retrospectively an algorithm for dealing with emergencies.[18] Frequent errors detected during this study suggest that such algorithms may be useful, and simulations promise to provide a way of determining if such algorithms improve performance. Unfortunately, we are not aware that this algorithm has been evaluated prospectively.

In fields other than anaesthesia, simulators have had a marked influence,[19 20] especially in the aviation and nuclear power industries. New theories have been developed to explain the way we identify, classify and react to critical incidents, based on research into human error and the psychology of crisis management. Previously published work using the ACCESS simulator[21] has shown that it can be used to investigate the mental processes anaesthetists use when dealing with emergencies and may allow new error reduction strategies to be developed and evaluated. Further work within the specialty of anaesthesia is needed to determine what the process of "giving an anaesthetic" entails and how the process may be made safer.

# Leakage of fluid past the tracheal tube cuff in a benchtop model

P. J. YOUNG, M. ROLLINSON, G. DOWNWARD AND S. HENDERSON

## Summary

We have assessed a range of high volume, low pressure (HVLP) cuffed tracheal tubes in a benchtop model, for leakage of fluid from above the cuff to the model trachea below, during various ventilatory modes. Rapid leakage occurred in the model during all modes of ventilation, unless tracheal pressure was greater than the height of fluid in the column above the cuff. This leakage occurred preferentially down longitudinal folds that occur in the HVLP cuff wall. This model suggests that, if a longitudinal fold within the cuff wall is patent, then the possibility exists of subglottic to tracheal leakage. (*Br. J. Anaesth.* 1997; **78**: 557–562).

**Key words**
Equipment, tubes tracheal. Model, trachea. Complications, pneumonia. Complications, aspiration. Intubation tracheal.

A tracheal tube with a high volume, low pressure (HVLP) cuff does not protect the lower airway from contamination by material leaking from the subglottis and above, in all circumstances, even with cuff pressure maintained at presently acceptable levels (25–30 cm $H_2O$).[1 2] It has been demonstrated *in vivo*, in patients whose tracheas were intubated with a tube with an HVLP cuff, undergoing general anaesthesia, that leakage occurred in 100% of cases, and this occurred down longitudinal folds within the cuff wall.[3] These folds always occur in an HVLP cuff on inflation within the trachea, as the diameter of the cuff must be greater than that of the trachea for intra-cuff pressure to be equal to tracheal wall pressure. Subclinical leakage of contaminated secretions around the cuff occurs in patients during mechanical ventilation in the intensive care unit (ICU), causing tracheal colonization and increasing the risk of ventilator-associated pneumonia.[4] The objects of this study were to identify the times during standard ventilatory patterns when the dynamic tracheal pressures below the cuff were such that leakage of fluid to the trachea was likely, and to identify aspects of management which are protective against leakage. We have quantified leakage rates in order to demonstrate that macro- (leakage of the order of ml $s^{-1}$) rather than micro-aspiration (leakage of the order of ml $h^{-1}$) can occur along a cuff channel.

## Materials and methods

### LUNG/TRACHEA MODEL

The patient model (fig. 1) consisted of a model lung (Vent Aid, TTL, Michigan Instruments Inc) with a Bear 3 ventilator driving the second mechanically linked bellows (model lung). This was linked to the distal artificial trachea to simulate a lung capable of spontaneous breaths. The artificial trachea was a silicone tube of 2.2 cm internal diameter (Laerdel Medical silicone extension tubing part No 87100) held vertically. The mean diameter of the adult male trachea is 2.2 cm,[5] and a size 8 tracheal tube is used commonly for adult male patients in intensive care practice. The pressure at the distal tip of the tracheal tube was measured via a central venous catheter used as a manometer and introduced through a connector at the proximal end of the tracheal tube. The manometer was filled with saline and transduced (using a Nihon Kohden Lifescope 8) with a saline–air interface. This dynamic pressure was found to be equal to the pressure recorded on a Bicore pulmonary monitor (CP100) placed within the tracheal segment proximal to the water trap.

Profile). Intra-cuff pressure was set at 25 cm $H_2O$ manually with a cuff inflator (Monitor control inflator, VBM, Medizintechnik), and was monitored continuously throughout the test. The proximal tracheal tube was connected to a Bird ventilator (6400ST volume ventilator), and continuous positive airway pressure (CPAP) 10 cm $H_2O$ was introduced via the Bird ventilator. When the pressure had stabilized, water coloured with methylene blue was added to the space above the cuff representing the subglottic space and above. The zero point was taken as the top of the cuff in contact with the artificial trachea. A set square and ruler fixed vertically alongside the artificial trachea allowed measurement from the zero point to the lower level of the meniscus. The water was added until a 10 cm head of pressure was achieved. The initial 10 cm $H_2O$ of CPAP was used to hold the fluid in the column above the cuff until the ventilator setting was made, and PEEP/CPAP was adjusted to several different levels (0, 2, 5 and 8 cm $H_2O$) for each ventilatory pattern. One experimenter set the PEEP/CPAP level and an observer blind to this read the level to which the meniscus decreased. The level to which the meniscus decreased was defined as the head of pressure resisted (HPR) for the given ventilatory pattern. All recordings were repeated five times. Inspiratory tidal volume was measured on the Bird internal monitor, and expiratory tidal volume was recorded with a 6800 Bird volume monitor in the expiratory ventilator tubing. Rate of leakage was measured by recording the rate of fall of the meniscus and calculating the volume of fluid lost. A selection of commercially available HVLP cuffed tubes was tested. The vertical model was used as measurement of the fluid column was easier, and water was used to simulate thin secretions.

### MODES EVALUATED

Trough pressure was defined as the minimum pressure recorded from the manometer pressure–time tracing at the tracheal tube tip during the inspiratory phase. In the spontaneous ventilation mode (SV), trough pressure was set by manipulating the driving ventilator (Bear 3) volume–flow settings, until the pressure trace at the distal tracheal tube was found to mimic that in a patient's trachea during SV (unpublished observations in human subjects). This was measured with the same technique during settled ($-2$ cm $H_2O$ trough pressure) and laboured ($-7$ cm $H_2O$ trough pressure) respiration (fig. 2). A spontaneous rate of 20 bpm was set on the driving ventilator. PEEP of 10 $H_2O$ was then introduced before instilling fluid above the cuff.

For the SV+pressure support (PSV) modes, trough pressure was set as above, then a PSV of 7 cm $H_2O$ and trigger sensitivity of 1 cm $H_2O$ were added. HPR during SV, PSV and intermittent positive pressure ventilation (IPPV) modes was recorded 20 min after reduction of CPAP/PEEP to the test level. This time was chosen because the column gradually decreased to an equilibrium level and was static with all ventilatory patterns after 20 min. In the IPPV mode there was no SV, tidal volume was 500 ml, breath rate was 15 bpm, the inspiratory:expiratory ratio was 1:2, and lung compliance was adjusted to create a peak inspiratory pressure at the ventilator of 20 cm $H_2O$.

### CUFFS AND CUFF PRESSURES TESTED

Unless stated otherwise a Portex Profile size 8 tube was used. Comparisons were also made between size 8 models of the Mallinckrodt Hi-Lo, Sheridan HVT, Portex Profile (all inflated to 25 cm $H_2O$) and the Bivona Fome Cuf. The Bivona Fome Cuf is a foam-filled HVLP cuff which is evacuated to allow insertion, and it relies on the distending pressure of the foam to seal the trachea. Rate of leakage was measured with a Portex Profile size 8 tube at intra-cuff pressures of 15, 25 and 60 cm $H_2O$. The effect of CPAP on the rate of leakage was assessed with a Portex Profile size 8 tube at a cuff pressure of 25 cm $H_2O$. HPR was assessed at cuff pressures of 25 and 60 cm $H_2O$ using the Portex Profile size 8 tube.

The effect of tracheal suctioning was also tested (using high suction from a hospital pipeline with a Clement's adapter, which generated a maximum negative pressure of $-400$ mm Hg), with open suction (through a 14CH catheter) and closed suction (Stericath 14F, Portex). The catheter was advanced 5 cm beyond the tracheal tube tip, then withdrawn over a 6-s period under suction. The addition of KY jelly to the cuff was also assessed by liberally coating the cuff with the jelly before intubation of the artificial trachea. The cuff was then tested using the SV, PSV and IPPV ventilatory modes described above, and with peak tracheal pressures of 80 cm $H_2O$ generated using a self-inflating bag (Ambu Resuscitator Mark III). Movement of the KY jelly coated cuff was assessed during IPPV ventilation by displacing the

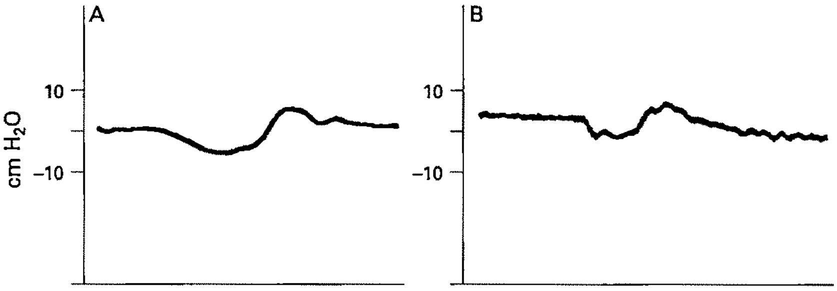

*Figure 2* Pressure profile measured by the central venous catheter with the tip at the distal end of the tracheal tube in (A) a patient and (B) the mechanical model.

tube along 4 cm of the length of the artificial trachea repeatedly (approximately 15 times) over a 6-h period.

STATISTICAL ANALYSIS

Mean and 95% confidence limits for rate of leakage and HPR were calculated (using a Casio scientific calculator), the confidence interval being SEM×1.96.

## Results

HPR remained the same with cuff pressures of 25 cm $H_2O$ compared with 60 cm $H_2O$ (fig. 5), that is 6.42 (6.38–6.46) cm compared with 6.46 (6.29–6.63) cm at 8 cm $H_2O$ of CPAP and 3.52 (3.33–3.71) cm compared with 3.52 (3.41–3.63) cm at 5 cm $H_2O$ of CPAP. However, the rate of flow past the cuff decreased when cuff pressure was increased from 25 to 60 cm $H_2O$, for example with a 3-cm $H_2O$ head of pressure above the cuff, the rate of leakage was 0.27 (0.21–0.33) ml $s^{-1}$ and 0.04 (0.03–0.05) ml $s^{-1}$, respectively (fig. 3).

CPAP and PEEP protected against leakage. Approximately 1 cm head of pressure was resisted for every 1 cm $H_2O$ that CPAP/PEEP was increased (fig. 6). This finding was true for all HVLP cuffs tested. HPR was significantly greater at each level of CPAP for the Mallinckrodt tube, apart from at zero pressure. With a CPAP of 5 cm $H_2O$, HPR for the Mallinckrodt tube was 4.66 (4.47–4.85) cm $H_2O$, significantly higher than HPR for the Portex tube (3.52 (3.33–3.71) cm $H_2O$). More negative trough pressures during spontaneous ventilation reduced HPR at all CPAP levels. With a CPAP of 5 cm $H_2O$, a decrease in trough pressure from −2 to −7 cm $H_2O$ reduced HPR from 3.22 (3.05–3.39) cm $H_2O$ to 2.08 (1.98–2.18) cm $H_2O$ (fig. 7). PSV of 7 cm $H_2O$ increased HPR to 5.56 (5.46–5.66) cm $H_2O$ and 3.52 (3.22–3.82) cm $H_2O$, respectively (fig. 8).

IPPV had a protective effect equivalent to approximately 1.5–2.5 cm $H_2O$ of PEEP/CPAP, for

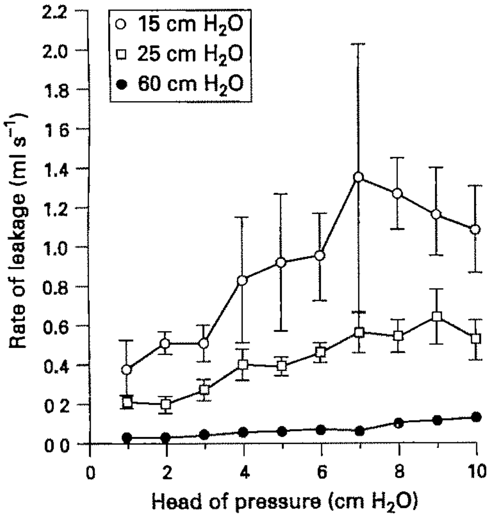

*Figure 3* Effect of cuff pressure (15, 25 and 60 cm $H_2O$) on rate of leakage of water past a Portex Profile size 8 tracheal tube (mean, 95% confidence intervals).

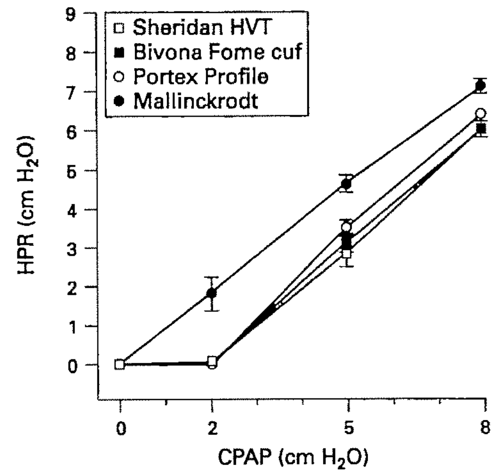

*Figure 6* Effect of cuff brand on the head of pressure resisted (HPR) at various CPAP levels using size 8 tracheal tubes (Sheridan HVT, Portex Profile and Mallinckrodt Hi-Lo at 25 cm $H_2O$, and the Bivona Fome Cuf) (mean, 95% confidence intervals).

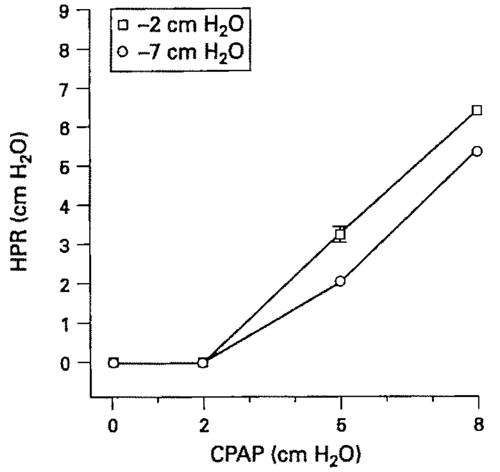

*Figure 7* Effect of spontaneous respiratory efforts on the head of pressure resisted (HPR) during simulated quiet respiration (inspiratory trough pressure of −2 cm $H_2O$) and simulated agitated respiration (inspiratory trough pressure of −7cm $H_2O$) at various CPAP levels using a Portex Profile size 8 tracheal tube at 25 cm $H_2O$ (mean, 95% confidence intervals).

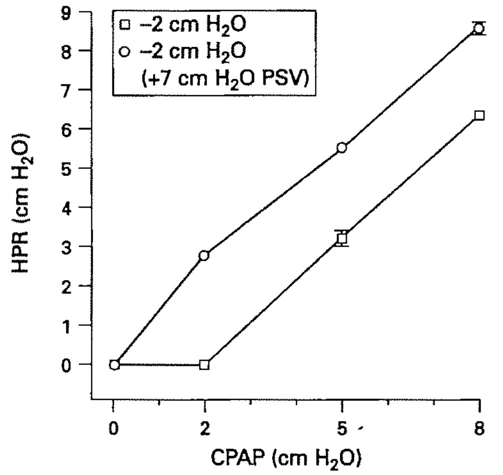

*Figure 8* Effect of pressure support ventilation (PSV) on the head of pressure resisted (HPR) during simulated quiet respiration (inspiratory trough pressure of −2 cm $H_2O$), at various CPAP levels using a Portex Profile size 8 tracheal tube at 25 cm $H_2O$ of cuff pressure (mean, 95% confidence intervals).

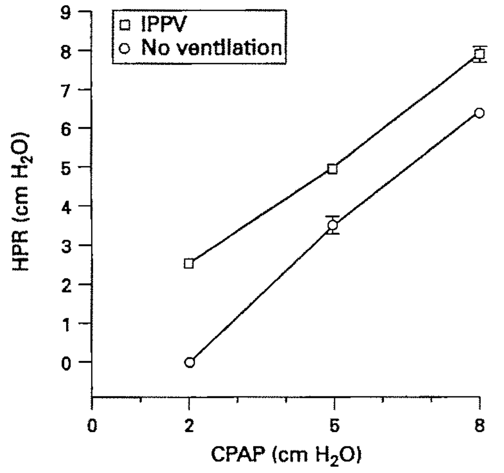

*Figure 9* Effect of intermittent positive pressure ventilation (IPPV) on the head of pressure resisted (HPR) at various CPAP levels using a Portex Profile size 8 tracheal tube at 25 cm $H_2O$ of cuff pressure (mean, 95% confidence intervals).

example at 5 cm $H_2O$ of CPAP/PEEP, IPPV increased HPR from 3.52 (3.33–3.71) cm $H_2O$, with no ventilation but constant CPAP, to 4.94 (4.82–5.06) cm $H_2O$ (fig. 9).

Neither open nor closed tracheal suctioning protected against generation of large negative tracheal pressures (less than −40 cm $H_2O$) or leakage of fluid in this model. Movement of the tube within the trachea caused minimal leakage. Loss of cuff pressure (to 15 cm $H_2O$) caused rapid leakage independent of CPAP. On deflation of the cuff, however, it was possible to expel some of the fluid out of the model, particularly at higher CPAP/PEEP levels (e.g. 15 cm $H_2O$). It was possible to ventilate the model for 24 h with no leakage (for example with an SV rate of 15 bpm, trough pressure −2 cm $H_2O$, PSV 7 cm $H_2O$ and PEEP 5 cm $H_2O$, and 4 cm of fluid above the cuff). After this period of no leakage, the tracheal tube was disconnected as is our practice for tracheal suctioning. At disconnection rapid leakage of fluid to the trachea occurred; this was increased with suctioning. Application of KY jelly to the cuff before intubation protected against leakage during all ventilatory modes studied. Application of high airway pressures during bagging, or movement of the tube over time, allowed a jelly filled channel to open, and leakage to occur. When a channel had cleared of jelly the leakage persisted over time.

## Discussion

This model of an intubated trachea did not attempt to simulate the surface of contact between the tracheal mucosa and the cuff, the static or dynamic properties of the tracheal and extra-tracheal tissues during ventilation, the properties of different consistencies of secretions or the effect of mucus on the cuff–tracheal interface. Fluids of different viscosities were not assessed and it is possible that rate of leakage would be reduced and HPR increased with viscous secretions. Within the confines of a benchtop model, this study suggests aspects of ventilatory management which are protective against leakage and aspects which make leakage more likely.

Leakage occurs down longitudinal folds within the cuff walls, and these folds formed in all HVLP cuffs tested. Testing different tubes showed that HVLP cuffs of a range of specifications all behaved similarly regarding leakage, the Mallinckrodt tube having a marginally but significantly higher HPR when CPAP/PEEP levels were greater than zero. This protective effect of the Mallinckrodt tube might be beneficial when the subglottic space is suctioned mechanically to reduce secretions above the cuff. Indeed, the rate of ventilator-associated pneumonia can be reduced with the use of mechanical subglottic secretion drainage and this cuff (Mallinckrodt Hi-Lo EVAC tube).[6]

Several factors increasing the possibility of leakage were identified. Tracheal suctioning through a 14CH catheter caused tracheal pressures to decrease to less than −40 cm $H_2O$ and caused rapid leakage. Increasing cuff pressure from 25 to 60 cm $H_2O$ decreased the rate of flow past the cuff, but did not increase HPR, so the column of fluid decreased to the same level ultimately, although it took longer to do so. Clinically, this exerts unacceptable pressures on the tracheal wall,[2] but it might be acceptable to increase cuff pressure for brief periods during times when the risk of leakage is greatest. A decrease in cuff pressure to 15 cm $H_2O$ caused rapid leakage; this can occur clinically with a leak from the cuff or pilot balloon, a change in tracheal compliance or a change in position or angle of the cuff within the trachea. The high variability of the data for flows at a cuff pressure of 15 cm $H_2O$ may have been caused by errors in measuring short time intervals, with high flows, using a stopwatch.

Aspects protective against leakage are those that increase the pressure head of fluid resisted above the cuff. CPAP and PEEP were protective (approximately 1 cm head of pressure was resisted for every 1 cm $H_2O$ of CPAP/PEEP for all cuffs), as was expected. This held for all HVLP cuffs tested, the Mallinckrodt cuff performing modestly better for a given CPAP level. If fluid builds up to above the level of CPAP/PEEP, then leakage occurs on a millilitre-for-millilitre basis as fluid is formed, provided the obligatory fold in the cuff is patent and not occluded with KY jelly or viscous secretions.

Application of KY jelly to the cuff before intubation was protective against leakage until an air leak developed. This air leak was small and not detectable on the inspiratory–expiratory tidal volume monitors. This suggests that the temporary plugging of the cuff channels by application of jelly before intubation could be beneficial in the short term.

More negative trough pressures ($-7$ cm $H_2O$) during spontaneous ventilation, representing laboured respiration (for example during testing for response to painful stimuli in an obtunded patient), reduced HPR at all CPAP levels and were therefore more likely to produce leakage. PSV protected against leakage during spontaneous respiration.

The protective effect of IPPV was equivalent to only a few centimetres of PEEP. HPR in the trough pressure of $-2$ cm $H_2O$+PSV group was higher than that of the IPPV group, which was higher than the no ventilation group for a given CPAP/PEEP. The reason for this might be because of a shorter expiratory phase in the $-2$ cm $H_2O$ trough pressure+PSV group than in the IPPV group, or the nature of the cyclical cuff compression with each ventilatory waveform.

The time (20 min) allowed for equilibrium in the ventilated groups was necessary because of the nature of the leak in the period before equilibrium was reached. A column of fluid would form in a fold, and a drop would drip into the distal model trachea initially with every ventilator cycle, then as the level approached equilibrium a drip would occur with increasingly less frequent cycles. Between each of these cycles the column within the fold would be expelled proximally with each increase of airway pressure, and form again when the distal tracheal pressure decreased. No further drops fell after a 20-min period.

Movement of the cuff within the trachea caused minimal leakage, but loss of cuff pressure (to 15 cm $H_2O$) caused rapid leakage independent of CPAP. It was possible, however, to expel some of the fluid out of the model, particularly at higher PEEP levels (e.g. 15 cm $H_2O$); this represents the clinical practice of those who apply PEEP or a large tidal volume on deflating the cuff at extubation.

In patients undergoing ventilation in the ICU with tracheal colonization, 85% were found to have identical microorganisms on both sides of the cuff.[6] It is likely that many cases of ventilator-associated pneumonia are a result of this route of contamination.[7] In ICU patients, up to 150 ml per day can be removed from the subglottic space by intermittent aspiration using a Hi-Lo EVAC tube (Mallinckrodt),[6] and in our experience with a patient prone, over 50 ml per hour at times could be collected dripping from the nose and mouth (unpublished observations). In supine or semi-recumbent patients, secretions do not overflow from the mouth, but pool in the oropharynx. When a pool has collected, further secretion production is presumably either inhibited, reabsorbed through oropharyngeal mucosa or drains into either the stomach or past the tracheal cuff. In this model, if fluid is added continually above the cuff, it continues to drain to the model trachea at the same rate, maintaining a constant pool above the cuff equal to the head of pressure resisted for that ventilatory pattern.

If this model represents the clinical situation then there are readily identifiable times when a patient with an intubated trachea aspirates subglottic fluid to the trachea, and manoeuvres that protect against this. Manoeuvres to reduce pressure differentials across the cuff, such as large tracheal tube diameters, better demand valves to avoid decreases in airway pressure and CPAP/PEEP would increase protection against leakage of subglottic fluid. This pool, however, would be available for leakage at any time during routine care when this protection was lost.

In summary, in an intubated model trachea, when a patent longitudinal fold exists in the HVLP cuff, there are identifiable times when gross leakage past the cuff occurs. This happens when the pressure difference across the cuff is favourable for flow to the trachea. Such clinical situations would be: (1) tracheal suctioning with 14CH catheters, either open or closed; (2) loss of cuff pressure; (3) loss of PEEP/CPAP such as disconnection from the ventilator; (4) continuing secretion production when the maximal protective effect of the particular ventilatory pattern has been reached; and (5) negative tracheal inspiratory pressures.

The possibility of leakage in this model is reduced when the pressure difference across the cuff favours flow from the trachea or the channels are blocked. This would occur with: (1) Trendelenburg position or subglottic aspiration before disconnection, extubation or suctioning the trachea; (2) maintaining CPAP/PEEP in the trachea, at all times; (3) use of PSV/IPPV and not allowing SV through a tube without support; (4) KY jelly lubrication on intubation; and (5) reduction in the subglottic and pharyngeal pool.

A new design of cuff in which folds are not present and wall pressure is maintained at acceptable levels would offer advantages. If such a cuff could be maintained at a tracheal wall pressure of 30 cm $H_2O$ reliably, then the barrier to fluid flow past the cuff would be at least equal to a HPR of 30 cm $H_2O$, and would withstand at least negative 30 cm $H_2O$ tracheal pressures. This would prevent leakage under most clinical circumstances. There is a need for the development of a tracheal tube cuff which protects against leakage, while exerting acceptable pressures on the tracheal wall.

# 5-HT spinal antinociception involves mu opioid receptors: cross tolerance and antagonist studies

C. S. Goodchild, Z. Guo, J. Freeman and J. P. Gent

**Summary**

The antinociceptive effects of intrathecal 5-HT, fentanyl, ICI197067 and U50488H were assessed by electrical current nociceptive threshold and tail flick latency measurements. Equieffective doses of these agonists were then given intrathecally with a range of doses of naloxone or the highly selective μ opioid antagonist, β-funaltrexamine. Antagonist dose–response curves were plotted. Other rats were made tolerant to either fentanyl or 5-HT by intrathecal injections of these drugs seven times daily and the antinociceptive effects of intrathecal fentanyl and 5-HT were assessed in each group. All intrathecal drugs caused spinally mediated antinociception in both tests. The antinociceptive effects of intrathecal 5-HT assessed by the electrical test (ECT) but not by tail flick latency (TFL) were suppressed by both opioid antagonists at doses similar to those required to suppress all of the effects of intrathecal fentanyl. The ED$_{50}$ values were 0.22 (fentanyl, ECT), 0.25 (fentanyl, TFL) and 0.18 (5-HT, ECT) μmol kg$^{-1}$ for naloxone and for β-funaltrexamine 2.2 fmol (5-HT, ECT), the same order as that required to produce similar suppression of the antinociceptive effects of fentanyl (46 amol: fentanyl, ECT; 4.6 fmol: fentanyl, TFL) and very different from the ED$_{50}$ for β-FNA suppression of the antinociceptive effects of the kappa opioid, U50488H (5.88 pmol). Cross tolerance in both directions was demonstrated between intrathecal fentanyl and 5-HT in the electrical test but not in the tail flick test. We conclude that intrathecal 5-HT caused spinally mediated antinociceptive effects revealed by electrical current and tail flick latency tests. The antinociceptive effects in the electrical test involved spinal cord μ opioid receptors. (*Br. J. Anaesth.* 1997; **78**: 563–569).

**Key words**

Pain, experimental. Pain, mechanisms. Pain, threshold. Serotonin (5-hydroxytryptamine). Antagonists opioid.

The antinociceptive effects of spinally administered 5-hydroxytryptamine (5-HT) are well established.[1–3] Spinal 5-HT probably mimics the activity of 5-HT containing fibres descending from neurones located in the brainstem raphe nuclei, electrical stimulation of which also produces antinociceptive effects in awake animals[4] and inhibition of responses to noxious stimulation of the skin in single dorsal horn neurones.[5] The 5-HT antagonist methysergide has been shown to reverse the antinociception produced by spinal 5-HT in addition to producing hyperalgesia in rats when used intrathecally alone.[3 6–11] These latter experiments imply that 5-HT receptors are involved in spinal antinociception.

Some electrophysiological studies have also suggested that opioid systems might be involved with these effects. Oliveras and colleagues[12 13] reported that electrical stimulation of the raphe nuclei could produce powerful antinociceptive effects in tests using noxious pinch and threshold of the jaw opening reflex in the cat and that naloxone could also completely abolish this antinociceptive effect in 12 of 16 cases. Similar observations were made by Akil, Mayer and Liebeskind[14] who, using tail flick latency measurements, found that antinociceptive effects caused by electrical stimulation of the periaqueductal grey matter in the rat could be partially reversed by the same opioid antagonist. The site of this opioid–serotonergic interaction (spinal cord or brain site) is uncertain and the interaction is also controversial as other groups have failed to confirm these results.[15 16]

The purpose of this study was first to confirm the involvement of opioid systems in 5-HT antinociception. Measurement of tail flick latency (TFL) and electrical current threshold (ECT) for nociception were the tests used. With this combination it is possible to demonstrate segmental or differential antinociceptive effects of intrathecally administered drugs thus proving that the action of the drug is confined to the caudal segments of the spinal cord responsible for tail innervation. This is achieved by showing increases in ECT in the tail after intrathecal drug administration without any change in the neck and it is possible to demonstrate simultaneously the effects of the drug on TFL.[17] We have investigated the actions of two opioid antagonists, naloxone and β-funaltrexamine, on spinally

mediated antinociceptive effects after intrathecal injection of 5-HT and selective opioid receptor agonists. This was followed by study of the occurrence of tolerance and cross tolerance between intrathecally administered 5-HT and fentanyl.

## Materials and methods

This work was carried out with permission of the licensing authorities of the UK (Home Office Licence PPL50/00131). In all experiments attention was paid to ethical guidelines for investigation of experimental pain in conscious animals.[18] Experiments were performed on 86 male Wistar rats (weight 150–200 g) with chronically implanted subarachnoid catheters, as described previously.[17] Measurement of ECT for nociception and TFL were used to demonstrate spinally mediated antinociceptive effects of intrathecally administered 5-HT, fentanyl ($\mu$ opioid agonist; Sublimaze; Janssen Pharmaceutical), ICI197067 and U-50488H ($\kappa$ opioid agonists; Sigma, London; Semat Technical Ltd, St Albans, UK). The conduct of the nociceptive tests and use of lignocaine (10 $\mu$l; 2%) to prove the intrathecal position of the catheter were as described in previous publications.[17 19 20] The responses to the drugs were standardized by expressing the threshold current as a ratio of the control (pre-drug) value as in previous studies, and TFL as a percentage maximum possible effect (% MPE) as follows[17 19 20]:

$$\%\,\text{MPE}=\frac{\text{mean TFL (post-drug)}-\text{mean TFL (pre-drug)}}{\text{cut-off time (10 s)}-\text{mean TFL (pre-drug)}}$$

### 5-HT DOSE–RESPONSE RELATIONSHIP

ECT measurements were made in the tail and neck in 54 experiments in which a range of doses of intrathecal 5-HT was administered (0.24–2.36 $\mu$mol; 50–500 $\mu$g). These data were used to establish the dose–response relationship for 5-HT in the ECT test. TFL was also measured in 28 of these experiments after intrathecal 5-HT (0.24–1.89 $\mu$mol; 50–400 $\mu$g). These measurements were used to establish the dose–response relationship for 5-HT in the TFL test. In 15 of the experiments the time course of the antinociceptive effects of 5-HT (300 $\mu$g; 1.41 $\mu$mol) was calculated as described previously.[17]

Data from this dose–response relationship and from previously published dose–response curves were used to choose the doses of agonists to be used in subsequent experiments; doses that were approximately equipotent and towards the top of the dose–response curve.[17 21 22] Thus the doses of intrathecal agonists used in subsequent experiments were: 5-HT 1.89 $\mu$mol; fentanyl 0.74 nmol; ICI 197067 1.5 nmol; U50488H 210 nmol.

### EXPERIMENTS WITH NALOXONE

To investigate the effects of naloxone on different agonists, experiments were performed with intrathecal 5-HT 1.89 $\mu$mol ($n$=58), fentanyl 0.74 nmol ($n$=30) and intrathecal ICI 197067 1.5 nmol ($n$=18). ECT and TFL measurements were made. The agonists were given intrathecally alone before and after a series of intervening experiments in which the same dose of intrathecal agonist was given after i.p. injection of naloxone (0.02–5.5 $\mu$mol kg$^{-1}$; 0.0075–2 mg kg$^{-1}$; dissolved in 1 ml of physiological saline). Percentage suppression of agonist effect by each dose of naloxone was calculated by the following expression:

$$\%\ \text{suppression}=\frac{R-r}{R-1}\times 100$$

where $R$=mean effect of agonist alone and $r$=effect of agonist in the presence of naloxone. Values for each dose of antagonist were combined to produce means (SEM) and plotted to produce naloxone dose–response curves as described previously.[22]

### EXPERIMENTS WITH $\beta$-FUNALTREXAMINE

A similar series of experiments was performed with the highly selective $\mu$ opioid antagonist, $\beta$-funaltrexamine $\beta$-FNA (Semat, St Albans, UK) in the dose range $10^{-18}$–$10^{-10}$ mol intrathecally[23–26] using 5-HT 1.89 $\mu$mol, fentanyl 0.74 nmol and U-50488H 210 nmol ($\kappa$-selective opioid) as intrathecal agonists. In each rat only one experiment was carried out for measurement of the antinociceptive effects of the agonist given alone and one (24 h later) for the effects of agonist with antagonist because of the irreversible nature of the block caused by $\beta$-FNA at $\mu$ opioid receptors.[24] Percentage suppression of the antinociceptive effects of each agonist by $\beta$-FNA was calculated as described above for naloxone, and $\beta$-FNA dose–response curves were plotted.

### CONTROLS

Five experiments were performed in which the effects of i.p. naloxone given alone (5.5 $\mu$mol kg$^{-1}$; 2.0 mg kg$^{-1}$; dissolved in 1 ml of physiological saline) were assessed in both the ECT and TFL tests. In another group, five rats with intrathecal catheters were given intrathecal $\beta$-FNA $10^{-10}$ mol alone and the effects assessed in both tests (ECT and TFL). These were the highest doses of antagonists used.

### TOLERANCE STUDIES

Forty-two rats with lumbar subarachnoid catheters were allocated to one of four groups. On the day after intrathecal cannulation the effect of intrathecal 5-HT 1.89 $\mu$mol on ECT and TFL were measured in groups 1 and 3, and the effect of intrathecal fentanyl 0.74 nmol on ECT and TFL was assessed in groups 2 and 4. On the next day, the effect of the same dose of fentanyl on ECT and TFL was measured in groups 1 and 3 and the effect of the same dose of 5-HT was measured in both tests in groups 2 and 4. For the next 3 days, the rats were treated as follows: (1) on each day, the 5-HT group ($n$=16) received seven intrathecal injections of 5-HT 1.89 μmol at hourly intervals; the effects of 5-HT on ECT and TFL were measured for the first of these injections each day; (2) on each day, the fentanyl group (*n*=16) received seven intrathecal injections of fentanyl 0.74 nmol at hourly intervals; the effects of fentanyl on ECT and TFL were measured for the first of these injections each day; (3) on each day, the control group of rats (*n*=5) received seven doses of 0.9% saline 5 μl (the vehicle for both drugs) intrathecally at hourly intervals and the effects of intrathecal 5-HT 1.89 μmol on ECT and TFL were measured once at the beginning of each day; (4) on each day, another control group of rats (*n*=5) received seven intrathecal injections of 0.9% saline 5 μl at hourly intervals and ECT and TFL responses were tested once at the beginning of each day with intrathecal fentanyl 0.74 nmol.

Thus in groups 1 and 2 attempts were made to induce tolerance to either 5-HT (1) or fentanyl (2). Groups 3 and 4 acted as controls receiving only saline intrathecal injections, except for one dose of agonist each day (5-HT, group 3; fentanyl, group 4) to assess the effects of the agonist in the ECT and TFL tests without frequent repeated dosing.

On the sixth day after cannulation the responses to 5-HT and fentanyl were measured again using both nociceptive tests so that they could be compared with the effects of both drugs on ECT and TFL measured on days 1 and 2 after cannulation. Thus changes in the effects of fentanyl in both nociceptive tests could be examined in animals made tolerant to 5-HT by repeated injections of this drug and vice versa for changes in 5-HT effects in fentanyl tolerant animals.

## Results

Intrathecal injection of 5-HT caused increases in ECT in the tail without any change in ECT in the neck (differential responses). These differential responses were used in the calculation of dose–response relationships.

### INTRATHECAL 5-HT DOSE–RESPONSE RELATIONSHIP

Figure 1 shows the dose–response relationship for intrathecal 5-HT in both nociceptive tests. Intrathecal 5-HT caused dose-related antinociceptive effects assessed by both tests. The dose of 0.9 μmol was the lowest dose which produced significant antinociceptive effects in the TFL test ($P$=0.0064; paired Student's *t* test) and in the ECT test ($P$=0.0046; paired Student's *t* test). Doses of 1.89 μmol and 2.36 μmol caused maximum antinociceptive effects in the TFL and ECT tests, respectively. Both doses caused differential responses.

Figure 2 shows the time course of the antinociceptive effects of intrathecal 5-HT 1.4 μmol assessed with the ECT and TFL tests. 5-HT caused significant increases in ECT in the tail with no change in ECT in the neck. There was also a simultaneous increase in TFL which lasted, as with the ECT change, for 20 min after intrathecal injection.

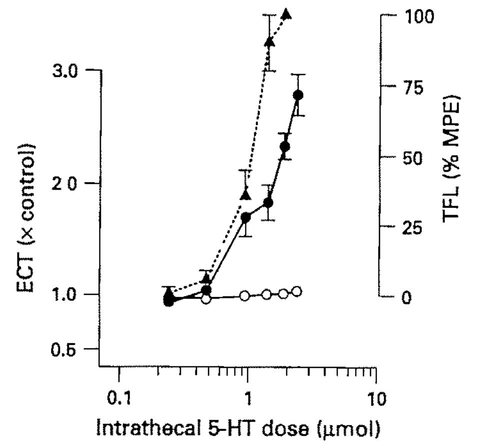

*Figure 1* Dose–response relationship for intrathecal 5-HT. Nociceptive thresholds were measured with increasing doses of intrathecal 5-HT (0.024–2.36 μmol) using the ECT (tail and neck) and TFL tests. Nociceptive thresholds were measured every 5 min for 15 min before and 30 min after intrathecal 5-HT. Responses for TFL measurements were expressed as percentage maximum possible effect (% MPE) and the increases in ECT values were expressed as a ratio of control (pre-drug) values for each set of electrodes. Values were grouped for each drug dose and are shown as mean, SEM (*n*=6–10). ▲=TFL; ●=ECT (tail); ○=ECT (neck).

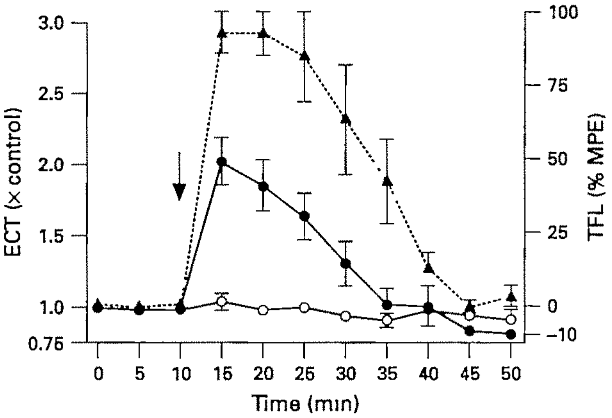

*Figure 2* Time response relationships for intrathecal 5-HT in the ECT and TFL tests. Each rat was given the same dose of intrathecal 5-HT 1.41 μmol (arrow). Each value of ECT (neck and tail) and TFL was standardized by dividing that value by the mean of the three values for that test at that site (neck or tail) taken before drug administration. These calculated values were then combined for each time and shown on the graph as mean, SEM (*n*=9). After injection of 5-HT (arrow) the antinociceptive effects occurred with both tests within 5 min and remained significantly above baseline for another 15–20 min ($P$<0.01, paired *t* test). ▲=TFL; ●=ECT (tail); ○=ECT (neck).

### EXPERIMENTS WITH NALOXONE

Naloxone i.p. caused dose-related suppression of the antinociceptive effects of fentanyl assessed in both the ECT and TFL tests (fig. 3). Naloxone i.p. also suppressed the antinociceptive effect of intrathecal 5-HT assessed by the ECT test. However, the antinociceptive effect of intrathecal 5-HT assessed by the TFL test was not affected by i.p. naloxone (fig. 3) although TFL measurements were made in the same experiments as those showing dose-related suppression of the increase in ECT. The values contributing to each curve were entered into a computer program (Statistica for Windows v 4.5) and doses

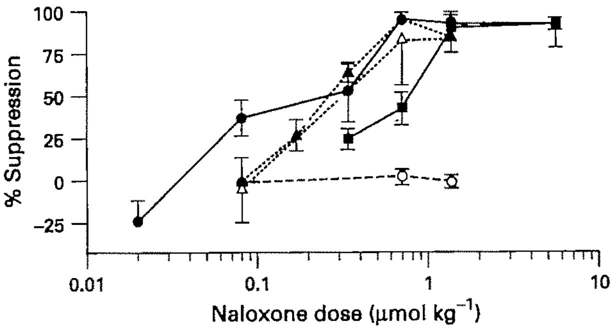

*Figure 3* Naloxone dose–response curves for suppression of the spinally mediated antinociceptive effects of intrathecal injections of fentanyl 0.74 nmol, ICI 197067 1.5 nmol and 5-HT 1.89 μmol. These doses of intrathecal agonist were equipotent in producing spinally mediated antinociception in the ECT test. They were given alone to establish a control response and then at the same time with a range of doses of naloxone i.p. The resulting reduction in response to the agonist in the ECT and TFL tests were calculated as percentage suppression of the response to agonist alone. Results for each dose of antagonist against each agonist were combined to produce mean, SEM ($n$=4–10). Naloxone caused dose-related suppression of 5-HT effects on ECT and all the antinociceptive effects of the opioids. Naloxone caused no suppression of 5-HT effects assessed by TFL. Higher doses of naloxone were needed to cause suppression of ICI 197067 antinociception compared with 5-HT and fentanyl, which were similar to each other. ●=5-HT ECT; O=5-HT TFL; ▲=fentanyl ECT; Δ=fentanyl TFL; ■=ICI197067.

were calculated that would produce 50% suppression of each agonist response (ED$_{50}$). These values were 0.22 (fentanyl, ECT), 0.25 (fentanyl, TFL) and 0.18 (5-HT, ECT) μmol kg$^{-1}$. Thus the ED$_{50}$ for i.p. naloxone that would cause 50% suppression of the antinociceptive effects of fentanyl assessed by both tests was similar to that causing 50% suppression of the effects of 5-HT in the ECT test. This is also the same value that was obtained previously in the same preparation[22] and it was much less than the dose of naloxone required to produce 50% suppression of κ opioid spinally mediated antinociception (the ED$_{50}$ for naloxone suppression of ICI 197067 was 0.64 μmol kg$^{-1}$, calculated with Statistica for Windows v 4.5) (fig. 3).

### EXPERIMENTS WITH β-FUNALTREXAMINE

β-FNA selectively antagonized the antinociceptive effects of the μ opioid fentanyl (fig. 4). Intrathecal β-FNA also caused dose-related suppression of the antinociceptive effect of 5-HT assessed by the ECT test but it did not cause any significant attenuation of the effect of intrathecal 5-HT on TFL measured in the same experiments. The ED$_{50}$ of β-FNA for suppression of the effects of 5-HT (ECT) was 2.2 fmol and of the same order as that required to produce similar suppression of the antinociceptive effects of fentanyl (46 amol: fentanyl, ECT; 4.6 fmol: fentanyl, TFL) and very different from the ED$_{50}$ for β-FNA suppression of the antinociceptive effects of the kappa opioid U50488H (5.88 pmol) (Statistica for Windows v 4.5).

The dose of U-50488H (210 nmol) used in these experiments caused a significant increase in tail ECT values (mean 1.71 (SEM 0.08), $P<0.05$) with no changes in neck ECT values; this increase was significantly less than the increases in tail ECT caused by the other drugs (2.35 (0.13), 5-HT; 2.1 (0.1), fentanyl; 2.3 (0.22), ICI197067) which were equieffective ($P>0.05$ unpaired *t* test). Although the dose of U-50488H was less efficacious than the other agonists, β-FNA only caused dose-related suppression of the antinociceptive effects of U-50488H at much higher doses of the antagonist than those effective at suppression of the effects of fentanyl and 5-HT (ECT).

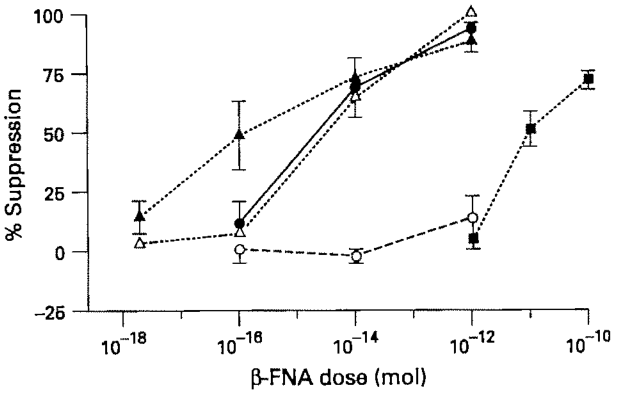

*Figure 4* Beta-funaltrexamine (β-FNA) dose–response curves for suppression of spinally mediated antinociceptive effects of intrathecal injections of fentanyl 0.74 nmol, U-50488H 210 nmol and 5-HT 1.89 μmol. These equipotent doses of intrathecal agonist were first given alone and in subsequent experiments mixed with the antagonist β-FNA. The response to the agonist was calculated as percentage suppression of the control agonist response and the values calculated for each dose of antagonist were combined to produce mean, SEM ($n$=5). The dose–response relationship for suppression of fentanyl TFL and ECT effects was similar to that for suppression of 5-HT effects assessed by the ECT test. There was no suppression of the TFL effects of intrathecal 5-HT even in those experiments in which doses of β-FNA were used that were sufficient to cause >90% suppression of the ECT response. Much higher doses of β-FNA were needed to suppress the effects of the κ-selective opioid agonist U-50488H. ●=5-HT ECT; O=5-HT TFL; ▲=fentanyl ECT; Δ=fentanyl TFL; ■=U50488H.

### TOLERANCE STUDIES

Figure 5A shows the development of tolerance to 5-HT in 5-HT-treated animals (group 1) compared with saline-treated animals (group 3). The response to intrathecal 5-HT (350 μg; 1.89 μmol) in the ECT test was reduced significantly in animals in group 1 after the first day's treatment of seven intrathecal injections of 5-HT 1.89 μmol ($P<0.0001$; paired *t* test). The response assessed by the TFL test, in the same group of animals with the same dose of 5-HT (fig. 5B), was reduced but was not significantly different from control. After the second day's treatment the response in the TFL test was significantly lower than that in the control measured in those rats on day 1 ($P=0.0358$; paired *t* test). However, these statistically significant differences for TFL measurements were not supported by comparison with *saline-treated* control animals ($P>0.05$; unpaired *t* test); this comparison did not support the occurrence of tolerance to intrathecal 5-HT in the TFL test. In contrast, it revealed highly statistically significant ($P<0.001$) diminution in responses to

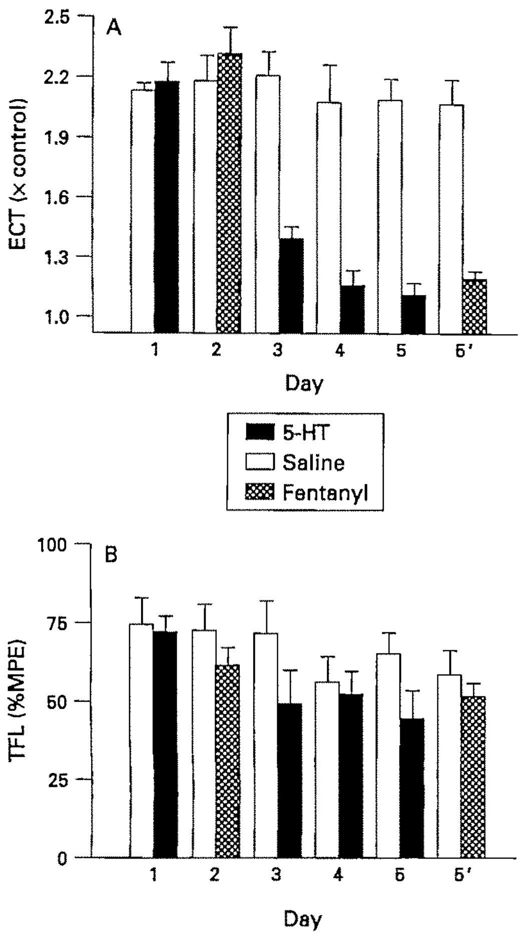

*Figure 5* Tolerance to intrathecal 5-HT. A: ECT responses in rats treated with intrathecal injections of 5-HT six times daily and saline. Responses on days 1, 3, 4 and 5 were measured at the beginning of the day to a single dose of 5-HT 1.89 μmol. The cross-hatched bars denote responses on days 2 and 5 (end of day 5 (5′)) to intrathecal fentanyl 0.74 nmol. B: The same procedure with 5-HT and fentanyl but results shown are for the TFL test. Results are mean, SEM ($n$=5 for saline-treated rats and $n$=10 for drug-treated rats).

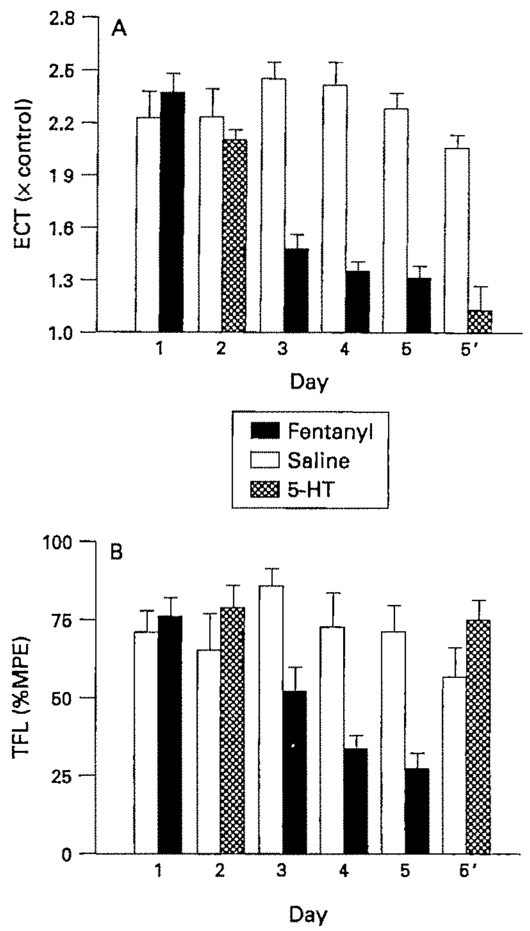

*Figure 6* Tolerance to intrathecal fentanyl. A: ECT responses in rats treated with intrathecal injections of fentanyl six times daily and saline. Responses on days 1, 3, 4 and 5 were measured at the beginning of the day to a single dose of fentanyl 0.74 nmol. The cross-hatched bars denote responses on days 2 and 5 (end of day 5 (5′)) to intrathecal 5-HT 1.89 μmol. B: The same procedure with fentanyl and 5-HT but results shown are for the TFL test. Results are mean, SEM ($n$=5 for saline treatment and $n$=10 for drug treatment).

intrathecal 5-HT on days 3, 4 and 5 in the ECT test. There was no significant change in responses to intrathecal 5-HT assessed by both tests in animals treated with repeated doses of saline throughout the study.

Similar experiments (fig. 6A, 6B) were performed using fentanyl 0.74 nmol as the agonist (group 2) compared with saline controls (group 4). After the first day's treatment of seven doses of intrathecal fentanyl at hourly intervals, responses to intrathecal fentanyl were reduced significantly compared with control responses in both tests ($P$<0.0001 in the ECT test and $P$=0.0068 in the TFL test; paired $t$ test). There was no significant change in the response in either test to intrathecal fentanyl in animals treated with seven intrathecal injections of saline at hourly intervals each day.

Animals who had become tolerant to intrathecal fentanyl by treatment with repeated intrathecal injections of fentanyl also showed a significant reduction in response to intrathecal injections of 5-HT, but only in the ECT test (fig. 6A). The response to intrathecal 5-HT 1.89 μmol was reduced from a mean control value of 2.08 (SEM 0.08) (ECT×control measured on day 1) to 1.1 (0.15) (ECT×control on day 5). In other words, no significant antinociception was produced on day 5. The effect of intrathecal injection of 5-HT on TFL was not changed significantly by fentanyl treatment ($P$=0.6022; paired $t$ test) (fig. 6B).

Animals rendered tolerant to intrathecal 5-HT as a result of repeated intrathecal injections of 5-HT 1.89 μmol exhibited a highly significant reduction in the response to fentanyl in the ECT test ($P$<0.0001; paired $t$ test) (see fig. 5A). In contrast, the response to fentanyl assessed by the TFL test was not significantly affected by repeated 5-HT treatment ($P$=0.358) (fig. 5B).

## Discussion

It is essential to demonstrate that a spinally administered drug is confined to the spinal cord in order to interpret results from whole animals in terms of action and interactions occurring at the spinal cord level. In the experiments described in this article, we have shown that the effects of drugs on ECT were differential or segmental. There were no disturbances in behaviour or locomotion in the presence of an increase in the current threshold for nociception in the tail without any change in the neck threshold. Therefore, we conclude that drug actions in all experiments where such differential effects occurred were confined to the caudal segments of the spinal cord where the drug was administered. As measurements of TFL were made at the same time, we may conclude that changes in TFL in these experiments were also the result of a spinal cord action of the drug, rather than the result of the drug spreading to the brain. Previous studies have shown that both TFL and ECT effects are caused by binding of 5-HT to spinal cord 5-HT receptors.[3 7 10]

Different stimuli (heat and electrical current) most likely activate different afferent pathways, and this study has revealed differences in the effects of intrathecal 5-HT on ECT and TFL. Different receptors seem to be involved at the level of the spinal cord. The classical way to analyse drug–receptor interactions is to construct a family of dose–response curves for a particular agonist at different known antagonist concentrations.[27] However, several of the conditions necessary for a valid analysis of this type could not be met in this situation. In particular, only drug doses, not concentrations, were known and the system was not at steady state. An alternative approach to analyse drug interactions with receptors and native neurotransmitter systems is to analyse antagonist dose–response curves,[28 29] that is to give a standard dose of drug and measure the effect in the presence of a range of doses of antagonist. In such an analysis, the position of an antagonist dose–response curve (the $ED_{50}$ for suppression of the effects of an agonist) is the same for suppression of the effects of an agonist drug that binds directly to a receptor as that for suppression of the effects of a drug that produces its effects by causing the release of a native neurotransmitter which binds with the same subtype of receptor to cause the final effect. Thus although naloxone is not a highly selective antagonist for the $\mu$ subtype of opioid receptor, it has been possible to demonstrate significant differences between naloxone dose–response curves for suppression of antinociceptive effects in the spine mediated by $\kappa$ opioid receptors compared with those mediated by $\mu$ receptors.[22]

In this study we demonstrated that naloxone caused dose-related suppression of the segmental antinociceptive effects of fentanyl assessed by both ECT and TFL tests and that these naloxone dose–response curves were coincident. This implies that both types of antinociception are mediated by fentanyl interacting with $\mu$ opioid receptors in the spinal cord. The naloxone dose–response curves for suppression of the effects of fentanyl on ECT and TFL were similar to those published previously ($ED_{50}$ approximately 0.2 $\mu$mol $kg^{-1}$); significantly different and to the left of naloxone dose–response curves for suppression of $\kappa$ opioid-mediated spinal antinociception.[22]

Naloxone also caused dose-related suppression of the increase in ECT produced by 5-HT but had no effect on 5-HT-induced TFL increases measured in the same experiments. This naloxone dose–response curve (5-HT, ECT effect) was coincident with both curves (ECT and TFL) for fentanyl, that is they overlay each other with approximately the same $ED_{50}$. The experiments with $\beta$-FNA confirmed the results of the naloxone experiments but were more convincing because of the greater selectivity of this antagonist for the $\mu$ opioid receptor.[24] The $\beta$-FNA dose–response curves for suppression of the effects of fentanyl on ECT and TFL and the effect of 5-HT on ECT were coincident and lay significantly to the left of the curve for suppression of the ECT effect of the $\kappa$ opioid U-50488H. In common with naloxone, $\beta$-FNA did not significantly attenuate the effects of 5-HT on TFL. Selectivity of $\beta$-FNA for the $\mu$ receptor was confirmed in these experiments because the dose of $\beta$-FNA which caused 50% suppression of the antinociceptive effects of fentanyl in both tests and the antinociceptive effects of 5-HT in the ECT test was approximately $10^{-15}$ mol whereas the dose needed to produce a similar amount of suppression of $\kappa$ opioid-mediated spinal antinociception was approximately $10^{-11}$ mol.

The results of the experiments using naloxone and $\beta$-FNA suggest that some of the antinociceptive effects of 5-HT in the spinal cord are mediated by activation of spinal cord opioid pathways involving $\mu$ opioid receptors. This only applies to the effects of 5-HT on ECT as the effects on TFL were not suppressed by naloxone or $\beta$-FNA. Naloxone is not highly selective for the $\mu$ receptor but $\beta$-FNA is a non-competitive antagonist, although it is highly selective for the $\mu$ opioid receptor. It is uncertain, therefore, if the antagonist dose–response curve analysis is valid with this drug even though the results confirm those obtained with naloxone. The tolerance experiments were therefore necessary.

The results from the tolerance studies are in agreement with those from the studies using antagonists. Cross tolerance for the effects of each agonist on ECT was produced. Thus induction of tolerance by repeated intrathecal injection of 5-HT led to a reduction in the increase in ECT caused by intrathecal fentanyl (fig. 5). The same was true of the animals treated with repeated intrathecal injections of fentanyl that led to progressive reduction in the antinociceptive effect of fentanyl assessed by both nociceptive tests. In these animals, induction of tolerance to fentanyl led to a decrease in the effect of 5-HT on ECT (fig. 6). No such cross tolerance occurred with the TFL test; 5-HT still caused an increase in TFL in fentanyl tolerant rats. These results suggest that desensitization of spinal cord $\mu$ opioid receptors may be caused either by repeated exposure to exogenous $\mu$ opioid agonist or by repeated release of an endogenous opioid agonist by exogenously applied 5-HT. This common $\mu$ opioid receptor is involved only with the antinociceptive effects of 5-HT and fentanyl measured in the ECT test and not those measured in the TFL test.

Therefore, these experiments support earlier observations of naloxone reversibility of 5-HT-mediated antinociception.[12 13] This may have implications for the development of clinical analgesic drugs acting at 5-HT receptors. Our results suggest that 5-HT-based analgesics could potentiate the antinociceptive action of spinal $\mu$-selective opioids. However, the full antinociceptive effect of such drugs may not be realized in opioid-tolerant individuals.

# Haemodynamic conditions enhancing gas embolism after venous injury during laparoscopy: a study in pigs†

J. E. BAZIN, T. GILLART, P. RASSON, N. CONIO, L. AIGOUY AND P. SCHOEFFLER

**Summary**

This study was designed to determine the conditions that promote carbon dioxide embolism after venous injury during laparoscopy in pigs. Injury to an iliac vein was filmed during laparoscopy in the presence of a pneumoperitoneum created at increasing pressures from 0 to 30 mm Hg in 5-mm Hg increments. At intraperitoneal pressures less than 20 mm Hg, there was a parallel increase in femoral venous pressures, resulting in haemorrhage, with persistent blood flow to the inferior vena cava. At intraperitoneal pressures of 20–30 mm Hg, there was collapse of the femoral vein, occurring earlier in the presence of hypovolaemia. Between these two states (haemorrhage and collapse), there was a point of equilibrium which allowed retrograde venous penetration of carbon dioxide bubbles. During release of the pneumoperitoneum, these bubbles were exteriorized through the area of the injury, but some passed into the inferior vena cava where their presence was detected by an oesophageal Doppler probe. (*Br. J. Anaesth.* 1997; **78**: 570–575).

**Key words**

Surgery, laparoscopy. Carbon dioxide, pneumoperitoneum. Complications, gas embolism. Measurement techniques, Doppler. Pig.

Laparoscopy is a routine method for diagnosis and treatment of gynaecological and intra-abdominal disease. Unfortunately, it may be associated with several complications, in particular gas embolism caused by carbon dioxide embolism. Several cases of carbon dioxide embolism have been reported,[1–3] with an incidence varying from 0.0013 to 0.59%.[4 5]

There are several studies on the physiological effects of experimental venous air embolism in the anaesthetized sheep[6 7] and on prevention of accidental venous air embolism in humans, notably in neurosurgery.[8] However, there are few data on the pathophysiology of spontaneous gas embolism via venous injury during laparoscopic pneumoperitoneum. Also, it is not known if the preventive measures recommended for neurosurgical procedures, such as increasing central venous pressure by fluid loading or by PEEP, are effective in preventing gas entry during laparoscopy.

The aim of this study was to investigate the pressure (both haemodynamic and intra-abdominal) at which venous gas penetration through a surgically opened iliac vein occurs during laparoscopy.

## Materials and methods

After obtaining institutional approval, we studied six domestic pigs, weighing 15–30 kg; they were premedicated with ketamine 6 mg $kg^{-1}$ i.m. and anaesthetized with propofol 3 mg $kg^{-1}$ i.v. The trachea was intubated and anaesthesia maintained with 0.75–1.5% isoflurane and 50% nitrous oxide in oxygen. Ventilation was controlled via a circle system (Cicero-Dräger) and adjusted to maintain end-tidal carbon dioxide pressure ($P\text{E}'_{CO_2}$) at 4.0–4.4 kPa. Neuromuscular block was maintained by intermittent doses of vecuronium. Core temperature was monitored continuously by rectal probe and maintained greater than 36 °C by a heated mattress. ECG and $P\text{E}'_{CO_2}$ were monitored continuously (Dräger PM 8010) throughout the study. The carotid artery, right internal jugular vein and femoral vein were cannulated with fluid-filled 1.7-mm catheters and connected to three pressure transducers (Abbott L978-39) to measure continuous arterial pressure (AP), femoral venous pressure (FVP) and central venous pressure (CVP). Only 4 cm of the femoral catheter was introduced, so that the tip would remain extra-abdominal at the level of the femoral vein. This was checked by dissection in each pig at the end of the study. For detection of venous gas embolism, a transoesophageal Doppler ultrasound flow probe (ODM II, Abbott-France Laboratories) was introduced. Its length corresponded to the distance measured between the dental arches and the xiphoid proces +5 cm. The probe was positioned facing the inferior vena cava. Correct positioning was checked by respiratory variations in signal intensity and quality of flow through the vena cava, and confirmed by femoral injection of

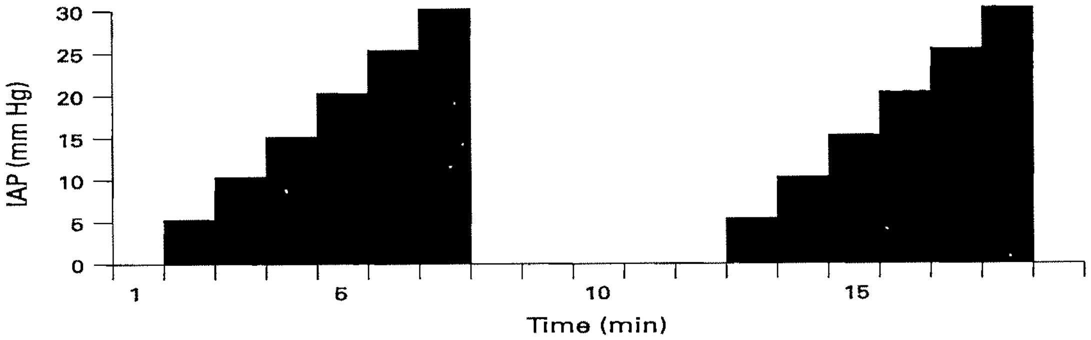

*Figure 1* Insufflation diagram: each pig underwent two cycles of pneumoperitoneum insufflation (IAP=intra-abdominal pressure) at pressures of 0 to 30 mm Hg, in increments of 5 mm Hg, each lasting 1 min. A 5-min interval separated the two cycles, which were followed by complete exsufflation.

2 ml of saline which was designed to induce a characteristic change in the signal recorded, after transient acceleration of venous flow.

During the first phase of the study, a carbon dioxide pneumoperitoneum was insufflated via a Verres' needle, at increasing pressures of 0–30 mm Hg in 5-mm Hg increments, using an automatic pressure flow insufflator (Stortz 26 430 BP). Mean AP, FVP, CVP and heart rate for each level of intra-abdominal pressure were noted after stabilization, and the pneumoperitoneum was then removed.

The second part of the study was undertaken after a stabilization period of 20 min. The pigs were placed in a moderate head-down position (10°) and the pressure transducers were repositioned so that they were level with the heart and femoral vein. A laparoscope (Stortz) was introduced via a 10-mm trocar inserted through a 1-cm supra-umbilical incision. As soon as the laparoscope was in place, it was connected to a camera, and the whole procedure was recorded on video–audio tape. Two additional trocars were inserted, under direct visual control, one in the lower left side of the abdomen for introduction of dissecting forceps, and the other into the right side for insertion of scissors. After dissection, the common iliac vein on the side opposite the femoral catheter was exposed and a vascular injury of a length of 3–4 mm (approximately half the diameter of the vein) was created. In three pigs (Nos 1, 3 and 5) blood loss was replaced by infusion of 500 ml of hydroxyethylstarch over 20 min. In the other three pigs (Nos 2, 4 and 6) blood loss was not replaced. Pneumoperitoneum was created with increasing pressures from 0 to 30 mm Hg in 5-mm Hg increments, each level of intra-abdominal pressure lasting at least 1 min. Each pig underwent two cycles of intraperitoneal insufflation separated by a 5-min interval. After each cycle, the peritoneum was completely emptied (fig. 1).

The presence of audible changes in the frequency of the Doppler signal was noted as evidence of gas embolism in the vena cava, and the point at which the changes occurred during each insufflation and exsufflation cycle was noted.

At the end of the procedure, correct positioning of the Doppler probe was confirmed by recording the characteristic signal displayed during injection of 1 cm$^3$ of carbon dioxide via the femoral venous catheter.

The effects of FVP, AP and CVP as a function of the insufflation pressures of the pneumoperitoneum were analysed by the Pearson linear regression test.

## Results

Five of the six pigs underwent two insufflation and exsufflation cycles at intraperitoneal pressures of up to 30 mm Hg. One pig died before the second cycle was completed (ventricular fibrillation, No. 4).

During the first phase of the study, during which intraperitoneal pressure was increased by 5-mm Hg increments, there was a parallel increase in FVP measured at the end of each level of intraperitoneal pressure. In all animals, FVP was always at least 4 mm Hg higher than intraperitoneal pressure. However, in pig No. 3, blood flow through the inferior vena cava, as detected by the Doppler probe, stopped at an intraperitoneal pressure of 30 mm Hg, while FVP did not exceed 31 mm Hg. In the six pigs, CVP increased very little and was not proportional to the increase in intraperitoneal pressure. Arterial

pressure and heart rate increased. The increase in FVP and AP correlated significantly with the increase in pneumoperitoneal insufflation pressures ($r=0.97$, $P<0.001$ and $r=0.85$, $P<0.05$, respectively). After exsufflation, AP returned to approximately its initial values, but tachycardia persisted (fig. 2). In pig No. 3, a decrease of 11% in AP was accompanied by cessation of blood flow through the inferior vena cava.

In the second part of this study (table 1), the venous injury was the cause of venous bleeding which persisted at intraperitoneal pressures less than 20 mm Hg (fig. 3A). Higher intraperitoneal pressures caused clearly visible venous collapse and bleeding. Venous air aspiration ceased as flow through the inferior vena cava stopped (fig. 3C). During the first cycle, this process was seen at 30 mm Hg in pig Nos 3, 2 and 6. During the second cycle, complete collapse was seen at 25 mm Hg in pig Nos 2 and 6, and at 30 mm Hg in pig Nos 1 and 3. Between these two levels of pressure, an equilibrium condition, characterized by the beginning of a collapse during expiration, was observed. During that period, bubbles of gas were clearly seen being aspirated intravascularly, in a retrograde manner towards the lower limbs (fig. 3B). During release of the pneumoperitoneum, these bubbles were seen to reappear and most were exteriorized with the haemorrhage (fig. 3D). However, some gas bubbles followed venous flow, causing the characteristic change in the Doppler signal. Four of the six pigs developed bubbles which were detected by Doppler during the procedure and were recorded during the 3 s, after exsufflation at the end of the cycle. In pig No. 2, gas embolization was also detected during the state of equilibrium.

There were no changes in $PE'_{CO_2}$ throughout the procedure, even when gas embolism occurred. These findings prompted us to carry out a third insufflation in pig Nos 3 and 5, at the pressure corresponding to the state of equilibrium between collapse and bleeding, for a duration of 5 min: in both pigs gas aspiration was clearly visible, and the characteristic change in the Doppler signal was recorded. Pig No. 3 displayed a decrease in $PE'_{CO_2}$ from 4.2 to 3.5 kPa accompanied by a 25% decrease in AP.

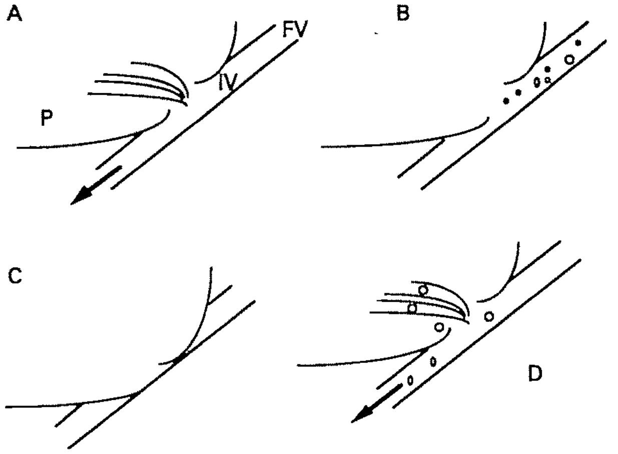

*Figure 3* Behaviour of a deperitonized iliac vein injury after insufflation of a pneumoperitoneum at increasing pressures, followed by exsufflation (IV=iliac venous, FV=femoral venous, P=pneumoperitoneum, o=carbon dioxide embolism). A: Persistent haemorrhage after iliac vein incision at intra-abdominal pressures less than 20 mm Hg; B: equilibrium state at intermediate intraperitoneal pressures, characterized by venous collapse during expiration and retrograde intravascular penetration of gas bubbles in four pigs; C: venous collapse and cessation of bleeding at high intra-abdominal pressures; D: exteriorization of carbon dioxide bubbles accompanied by bleeding during release of the pneumoperitoneum and detection of emboli in the inferior vena cava.

## Discussion

We chose to expose the iliac vein after peritoneal dissection, because of its size and accessibility. Furthermore, the technique is easily reproducible. However, caution should be exercised in any extrapolation of these results to humans, because the iliac vein is normally less sensitive to variations in intraperitoneal pressure than the vessels normally exposed during laparoscopy. We did not measure transmural pressures in the right atrium, because direct measurement of intravascular pressures constitutes the only true measure of blood flow and its direction.

In this study, FVP increased with increasing intraperitoneal pressure, thus maintaining blood flow through the inferior vena cava, up to levels of 25 mm Hg. Intraperitoneal pressures greater than 25 mm Hg resulted in venous collapse, which occurred at lower levels of intraperitoneal pressure in the presence of hypovolaemia. Our findings are in agreement with previous studies on the haemodynamic effects of pneumoperitoneum with or without hypovolaemia. Rubinson and co-workers described parallel increases in intraperitoneal and abdominal vena cava pressures after intraperitoneal perfusion of liquid. At pressures of 29–42 mm Hg, they demonstrated collapse of the transdiaphragmatic vena.[9] Jorgensen and colleagues reported in pigs a decrease in femoral venous blood flow concomitant with an increase in intraperitoneal pressure from 5 to 20 mm Hg, but with no cessation of blood flow at the highest level of pressure.[10] In dogs, Ivankovich and co-workers found that insufflation of a pneumoperitoneum at 40 mm Hg reduced cardiac and vena caval blood flow by 60%, but FVP remained consistently greater than intraperitoneal pressure.[11] In two groups of pigs, with and without hypovolaemia, Ho and colleagues found that the hypovolaemic group were more acidotic and hypercapnic after pneumoperitoneum, with a persistent but smaller increase in AP and unchanged cardiac index.[12] In dogs, with vena caval pressure kept constant by cardiopulmonary bypass, Takata, Wise and Robotham investigated the effects of a moderate increase in intra-abdominal pressure. During hypervolaemia, there was an increase in vena caval blood flow caused by splanchnic redistribution of blood from the liver. In hypovolaemic animals, the decrease in transmural pressure of the transdiaphragmatic vena cava resulted in partial collapse of the latter with a decrease in venous return. However, FVP increased in parallel with the pressure in the vena cava.[13] These results confirm that the variations in intraperitoneal pressure and FVP are the main determinants of vascular wall movements responsible for venous collapse and bleeding, and that between these two extremes there is a situation which may facilitate gas embolization. The filling pressures of the right heart, which provides an approximate measure of volaemic status, thus plays an indirect role in determining the threshold for venous collapse. The intrinsical tone of the venous wall seems to play no role in these changes. With respect to the lower vena cava, the parietal component involved in venous collapse has been assessed at only 1 mm Hg.[13]

The incidence of gas embolism during laparoscopic surgery varies widely. No embolism was detected by precordial Doppler monitoring during 61 laparoscopic cholecystectomy procedures.[14] However, Thio and Reichert reported systematic appearance of emboli in seven patients monitored by transoesophageal echocardiography.[15] With the same monitoring system, Derouin and colleagues also detected 11 cases of gas embolism in 16 patients.[16] Various multicentre investigations of incidents during laparoscopic surgery show that gas embolism is a prime suspect in most "cardiovascular" collapse occurring during laparoscopy.[17]

Most of the serious cases of gas embolism reported in the literature occur at the beginning of an operation, because of intravascular insufflation caused by incorrect positioning of the insufflation needle. The cases reported to have occurred in the middle or at the end of surgery involve other mechanisms. According to some authors, embolism can occur after peritoneal absorption of gas with accumulation in the portal system and secondary mobilization during changes in position or after abdominal decompression.[18] However, this suggestion has not been confirmed and seems less probable than embolization of gas from the peritoneal cavity after venous damage during surgical dissection. Some of these delayed embolic episodes may represent gas bubbles which have been aspirated in a retrograde manner at the time of perioperative venous injury. Our findings support this mechanism, especially in cases when the conditions created by serious injury to a major vessel occur at intraperitoneal pressures greater than 15 mm Hg.

Transoesophageal Doppler can detect air emboli as small as 0.05 ml[19] with no haemodynamic changes or change in $P\mathrm{E}'_{\mathrm{CO}_2}$, which usually detects an embolus volume of 1 ml kg$^{-1}$.[20 21] However, in the presence of rapid variations in intraperitoneal pressure and if favourable haemodynamic conditions persist, we may expect larger degrees of air emboli. This occurred in one of the two pigs in which we maintained a pneumoperitoneum at the equilibrium pressure for 5 min. The possibility of a Venturi effect suggested by some authors[22] at low intraperitoneal pressures was not confirmed by our study.

Most of the prophylactic measures to combat venous gas embolism have been developed during neurosurgery performed with the patient in the sitting position, and thus are aimed at avoiding aspiration of air through the dura mater venous sinuses. All methods involve increasing the pressure in the venous sinuses above atmospheric pressure, such as vascular filling, introduction of PEEP or the use of antishock trousers. However, these methods are controversial, for example PEEP may also increase the risk of paradoxical gas embolism, as right atrial pressure may become higher than the left, thus allowing a shunt to develop in the presence of a patent foramen ovale, which is present in 10–30% of patients in the general population.[23–26] This risk is accentuated by the fact that gas embolism increases CVP when it reaches the pulmonary circulation. Volumes of approximately 2 ml kg$^{-1}$ may reverse the pressure between the left and right cavities.[27 28] During laparoscopy, all of these prophylactic methods are of no avail. We have shown that the risk of air embolism remained low if intraperitoneal pressure was less than 15 mm Hg.

In cases where severe vascular injury causes serious haemorrhage, it is risky to increase intraperitoneal pressure in order to stop gas aspiration or haemorrhage and thus allow time for laparoscopic repair of the injury. The intraperitoneal pressure required may be so high that it may have harmful cardiovascular effects, especially a decrease in cardiac output because of reduction in venous return. In addition, we cannot be sure that such conditions would not favour massive gas aspiration. However, if such an increase in intraperitoneal pressure is warranted, close monitoring of haemodynamic state and continuous cardiac auscultation with a transoesophageal Doppler probe is necessary in order to detect possible gas embolism, until the pneumoperitoneum is evacuated.

# Increased intraperitoneal pressure up to 15 mm Hg does not reliably induce haemodynamic changes in pigs

C. LENTSCHENER, D. BENHAMOU, K. M'JAHED, M. MOUTAFIS AND M. FISCHLER

## Summary

Haemodynamic alterations occur consistently with laparoscopic surgery in humans. These haemodynamic changes have never been reproduced in an animal model without additional potentiating factors. As these alterations may be deleterious in some patients and as the cause is only partly understood, we have used an animal model to study these changes. Pneumoperitoneum with intraperitoneal pressures of up to 15 mm Hg were produced in pigs, in the same way as for laparoscopic surgery in humans. Arterial pressure, cardiac output, pulmonary arterial pressure and systemic arterial resistance were assessed at baseline and after pneumoperitoneum had been produced. Intraperitoneal pressures of up to 15 mm Hg were not associated with consistent circulatory changes and we conclude that haemodynamic changes associated with laparoscopic surgery are dependent on species. (*Br. J. Anaesth.* 1997; **78**: 576–578).

**Key words**
Carbon dioxide, pneumoperitoneum. Surgery, laparoscopy. Cardiovascular system, effects. Pig. Model, pig.

Haemodynamic changes occur consistently in humans during laparoscopic surgery, even though intraperitoneal pressure (IPP) is maintained at less than 15 mm Hg.[1] It is unlikely that these haemodynamic changes are entirely related to decreased venous return, direct compression of the abdominal aorta secondary to increased IPP[2] or transperitoneal absorption of carbon dioxide. It has been suggested that baroreflexes elicited by intra-abdominal viscera stimulation are involved.[3] In an attempt to evaluate this latter hypothesis, we created pneumoperitoneum in pigs in the same way as for laparoscopic surgery in humans.[1] The pig haemodynamic system has been shown to resemble the human system.[4]

## Materials and methods

After obtaining approval from the Institutional Animal Care Committee, two adult domestic pigs (mean weight 40 (SD 0.5) kg) and six piglets (18.1 (1.9) kg) were anaesthetized with ketamine i.m. and continuous infusion of fentanyl and pancuronium, and their lungs ventilated mechanically (Cicero mechanical ventilator, Dräger SA, France) with 50% nitrous oxide in oxygen after tracheal intubation. Tidal volume was set at 10 ml $kg^{-1}$. Ventilatory frequency was adjusted to maintain end-tidal carbon dioxide partial pressure ($PE'_{CO_2}$) at 4.5±0.3 kPa. Lactated Ringer's solution was infused at 500 ml $h^{-1}$. The carotid artery was cannulated for monitoring systemic arterial pressure (AP) and for blood sampling. The right external jugular vein was cannulated with a 7-French pulmonary artery thermodilution catheter. Pulmonary arterial pressure (PAP), pulmonary capillary wedge pressure (PCW) and cardiac output (CO) were measured (Marquette electronics, France). SVR (dyn $s^{-1}$ $cm^{-5}$) was calculated using the standard formula. Peritoneal insufflation with carbon dioxide was performed slowly up to 15 mm Hg, at a rate of 250 ml $min^{-1}$, via a Palmer needle placed percutaneously into the abdominal cavity with an insufflator allowing continuous monitoring of IPP (Laparoflator FM, Wiest KG, Germany). Haemodynamic measurements were obtained after a 15-min period of stabilization: at baseline after induction of anaesthesia and at an insufflation level of 15 mm Hg. Body temperature was maintained at 36 °C.

Mean values were analysed using a paired Student's *t* test. Significance was set at $P<0.05$.

## Results

Intraperitoneal insufflation was not associated with any significant changes in either AP ($P=0.59$), CO ($P=0.62$) or SVR ($P=0.63$) (table 1).

## Discussion

PAP and PCW increased as a consequence of increased intrathoracic pressure associated with establishment of pneumoperitoneum.[1] However, our study failed to reproduce those changes usually observed in humans (i.e. increase in AP and SVR;

decrease in CO).[1] The pig model was chosen as this animal is related to humans, both physiologically and anatomically. Its cardiovascular system is similar with respect to the size and distribution of coronary vessels, arterial pressure, heart rate, cardiac index, regional distribution of carbon monoxide and maximum oxygen consumption.[4] However, examination of many studies conducted in animals to reproduce haemodynamic disturbances associated with increased IPP, shows discrepancies between studies for every level of IPP and even for baseline measurements. Moreover, haemodynamic changes similar to those in humans during laparoscopic surgery have never been reproduced in animals without additional potentiating factors: IPP increased to more than 20 mm Hg and in some studies up to 40 mm Hg[5]; hypovolaemia or a vasodilating agent, or both[6]; hypercapnia or acidosis[7]; and coexisting thoracic incision for haemodynamic investigation.[8] In published studies, IPP has been increased by various physical methods: carbon dioxide or nitrogen insufflation,[8] external counterpressure of the abdominal wall,[9] intraperitoneal fluid infusion[1] and intra-abdominal implantation of an inflatable bag.[10] Indeed, regional differences in abdominal pressure have been described when IPP is increased by methods other than intraperitoneal gas or liquid insufflation.[11] Moreover, a vascular reflex might have been elicited in some procedures by compression or distension of intraperitoneal viscera.[3] Only two animal species, dogs and pigs, have been assessed and in almost all studies, animals have been anaesthetized with either pentobarbitone or fentanyl, both of which are unlikely to upset haemodynamic changes observed in humans during laparoscopic procedures.[12]

It is questionable if the drugs given to our pigs may have affected the data. Ketamine stimulates the sympathetic system[13] causing increases in AP and SVR. As increases in AP and SVR were the main haemodynamic changes expected, and as no increases in AP or SVR occurred even in the presence of possible co-existing sympathetic stimulation induced by ketamine, we conclude that ketamine had no effect.[13] Fentanyl stimulates the parasympathetic system[14]; therefore fentanyl may have impaired the expected haemodynamic changes. However, continuous infusion of fentanyl has been shown to cause minimal haemodynamic changes[14] and is unlikely to have completely masked the anticipated findings. Pancuronium produces tachycardia via parasympathetic block. However, this effect is weak and is unlikely to have impaired the expected haemodynamic effects of increased IPP. We did not study IPP at values greater than 15 mm Hg, but several studies using higher IPP (up to 40 mm Hg) failed to reliably reproduce haemodynamic changes associated with pneumoperitoneum in humans.[5]

In our investigation, peritoneal insufflation and pressure control were assessed with an insufflator validated for this use. Haemodynamic assessment with a thermodilution pulmonary artery catheter is a routine and reliable technique in animal and human investigations. Body temperature and $P\text{CO}_2$ were maintained within the physiological range and fluid status was monitored closely. Our sample size may have been too small to draw definitive conclusions, but no consistent trend occurred in haemodynamic changes. In accordance with previous studies,[5 7] inclusion of two adult pigs in the study suggests that maturity is not a major factor.

In summary, we believe that our study, in accordance with previous similar studies, provides the following information: (a) haemodynamic changes associated with laparoscopic surgery in humans cannot reliably be reproduced in a pig model; (b) haemodynamic disturbances associated with IPP are dependent on species; (c) extrapolation to humans of data recorded in animal models during laparoscopic procedures must be made with caution.

# *In vivo* assessment of droperidol-induced bronchial relaxation in dogs using a superfine fibreoptic bronchoscope

N. OTOMO, K. HIROTA, T. SATO, Y. HASHIMOTO AND H. ISHIHARA

## Summary

Droperidol has been reported to cause bronchodilatation but its mechanism(s) of action is unknown. We have evaluated the spasmolytic effect of droperidol on histamine- and serotonin (5-HT)-induced bronchoconstriction in dogs. Bronchial cross-sectional area was assessed with a superfine fibreoptic bronchoscope. Twenty-eight mongrel dogs were allocated randomly to one of two groups (histamine and 5-HT) to receive either histamine or 5-HT to induce bronchoconstriction. Changes in bronchial cross-sectional area were presented as percentage of basal bronchial cross-sectional area. Continuous i.v. infusion of histamine 500 $\mu$g kg$^{-1}$ h$^{-1}$ or 5-HT 500 $\mu$g kg$^{-1}$ h$^{-1}$ decreased percentage bronchial cross-sectional area by 46.4 (14.3) % or 68.9 (13.7) %, respectively. In both groups, droperidol reversed bronchoconstriction in a dose-dependent manner. In the histamine but not in the 5-HT group, plasma adrenaline and noradrenaline concentrations increased significantly after i.v. droperidol. In addition, propranolol antagonized droperidol-induced relaxation in the histamine but not in the 5-HT group. Our data indicate that the spasmolytic effect of droperidol on canine airway was caused, at least in part, by both catecholamine releases and 5-HT receptor antagonism. (*Br. J. Anaesth.* 1997; **78**: 579–582).

**Key words**
Lung, bronchus. Pharmacology, droperidol. Equipment, bronchoscopes Dog.

Droperidol is an effective agent for the treatment of status asthmaticus.[1] The bronchodilating effect of droperidol may be mediated via $\alpha_1$-adrenoceptor block,[1] catecholamine release[2 3] and serotonin (5-HT) receptor antagonism.[4–6] Gentil and colleagues demonstrated that droperidol prevented 5-HT- but not histamine-induced bronchospasm in guinea pigs.[4] In contrast, we have reported previously that droperidol inhibits tracheal contraction induced by both 5-HT and histamine.[6] Gentil and colleagues[4] evaluated bronchospasm by measuring respiratory conductance, a classical indirect measure with low sensitivity and reliability.[7 8] We have developed a direct method to quantify bronchial calibre using a superfine fibreoptic bronchoscope with increased sensitivity compared with measures of airway resistance, dynamic pulmonary compliance and airway pressure.[9 10] In this study, we have assessed *in vivo* the spasmolytic effects of droperidol on histamine- and 5-HT-induced bronchoconstriction in dogs by measuring airway calibre using a fibreoptic bronchoscope.

## Materials and methods

After approval of our Animal Experiment Committee, 28 mongrel dogs, weighing 8–12 kg, were anaesthetized with pentobarbitone 30 mg kg$^{-1}$ i.v. and paralysed with pancuronium 200 $\mu$g kg$^{-1}$ h$^{-1}$ i.v. The trachea was intubated using a tracheal tube (internal diameter 7.0 mm; Fuji system, Tokyo, Japan) with an additional small lumen for insertion of a superfine fibreoptic bronchoscope with an outer diameter of 2.2 mm (OES Angiofiberscope AF type 22A, Olympus, Tokyo, Japan) to monitor continuously bronchial cross-sectional area. The tip of the fibrescope was located between the second and third bifurcation of the right lung. Fibreoptic image of bronchial cross-sectional area was printed via a videoprinter (Videoprinter VY-170, Hitachi, Tokyo, Japan) and measured with an NIH image program which is well established and widely used (written by Wayne Rasband at the US National Institutes of Health and available from the Internet by anonymous ftp from zippy. nimh. nih. gov. or on floppy disk from NTIS, 5285 Port Royal Rd., Springfield, VA 22161, part number PB93-504868). Changes in bronchial cross-sectional area were represented as percentage of basal bronchial cross-sectional area (assessed before bronchoconstrictor infusion). The lungs were ventilated with an animal ventilator (AR-300, Acoma, Tokyo, Japan) and end-tidal carbon dioxide was maintained continuously at 4.5–5.0% before induction of bronchoconstriction. Systemic arterial pressure was monitored continuously via a femoral arterial cannula which was also used for blood sampling. A pulmonary artery catheter was inserted via the femoral vein to administer drugs and

to infuse lactate Ringer's solution 4 ml $kg^{-1}$ $h^{-1}$. Dogs were allocated randomly to one of two groups; 14 dogs received histamine to induce bronchoconstriction (histamine group) and the remaining 14 dogs received 5-HT (5-HT group).

### HISTAMINE GROUPS

Bronchoconstriction was induced with a bolus dose of histamine 10 μg $kg^{-1}$ i.v. followed by an infusion of 500 μg $kg^{-1}$ $h^{-1}$ via the pulmonary artery catheter. Systolic arterial pressure was maintained greater than 80 mm Hg with infusion of fluid 50 ml $kg^{-1}$ and with continuous infusion of phenylephrine 0.5–2.0 μg $kg^{-1}$ $min^{-1}$ at a rate dependent on systolic arterial pressure and which could not significantly affect histamine-induced bronchoconstriction.[10] Thirty minutes later, when stable bronchoconstriction was achieved, droperidol was given i.v. Seven of the 14 dogs were given each dose of droperidol: 0 (saline), 0.01, 0.1 and 1.0 mg $kg^{-1}$ i.v. (histamine–droperidol group), and the remaining seven dogs were given droperidol 0 and 1.0 mg $kg^{-1}$ followed by 100 μg $kg^{-1}$ of propranolol (histamine–droperidol–propranolol group). In both groups, bronchial cross-sectional area was assessed before and 30 min after the start of histamine infusion and 5 min after administration of each dose of droperidol and propranolol. At least 15 min elapsed between administration of each dose. Arterial blood was obtained simultaneously with bronchial cross-sectional area assessments for measurement of plasma concentrations of adrenaline and noradrenaline in the histamine–droperidol group. Log-dose–response curves were constructed using DeltaGraph Pro. (DeltaPoint, Inc. 1992). Plasma adrenaline and noradrenaline concentrations were measured by gas chromatography–mass spectrometry.[11]

### 5-HT GROUPS

In the 5-HT groups, bronchoconstriction was induced with a bolus of 5-HT 10 μg $kg^{-1}$ i.v. followed by an infusion of 500 μg $kg^{-1}$ $h^{-1}$. Seven dogs were included in the 5-HT–droperidol group and the remaining seven dogs in the 5-HT–droperidol–propranolol group. The remainder of the study was as described for the histamine groups.

### ANALYSIS OF DATA

All data are expressed as mean (SD). Statistical analyses were by repeated-measures ANOVA followed by Fisher's protected least significant difference test for the histamine and 5-HT–droperidol groups, and by Scheffé's *F* test for the histamine and 5-HT–droperidol–propranolol groups. $P<0.05$ was considered significant.

## Results

### HISTAMINE GROUP

In the histamine–droperidol group, histamine decreased percentage bronchial cross-sectional area by 46.4 (14.3) % (fig. 1A). Droperidol produced a dose-dependent increase in percentage bronchial cross-sectional area (i.e. bronchodilatation) with an $ED_{50}$ of 0.157 (0.108) mg $kg^{-1}$; 1.0 mg $kg^{-1}$ produced full reversal of histamine-induced bronchoconstriction. Plasma adrenaline and noradrenaline concentrations also increased significantly in a dose-dependent manner (fig. 2). In the histamine–droperidol–propranolol group, histamine decreased percentage bronchial cross-sectional area by 35.7 (14.0) % which was reversed by droperidol (percentage bronchial cross-sectional area 98.4 (15.1) %). Propranolol 100 μg $kg^{-1}$ fully reversed the increase in bronchial cross-sectional area induced by droperidol (fig. 1B).

### 5-HT GROUP

5-HT decreased percentage bronchial cross-sectional area by 77.1 (13.0) % in the 5-HT–droperidol group and by 68.9 (13.7) % in the 5-HT–droperidol–propranolol group. Droperidol

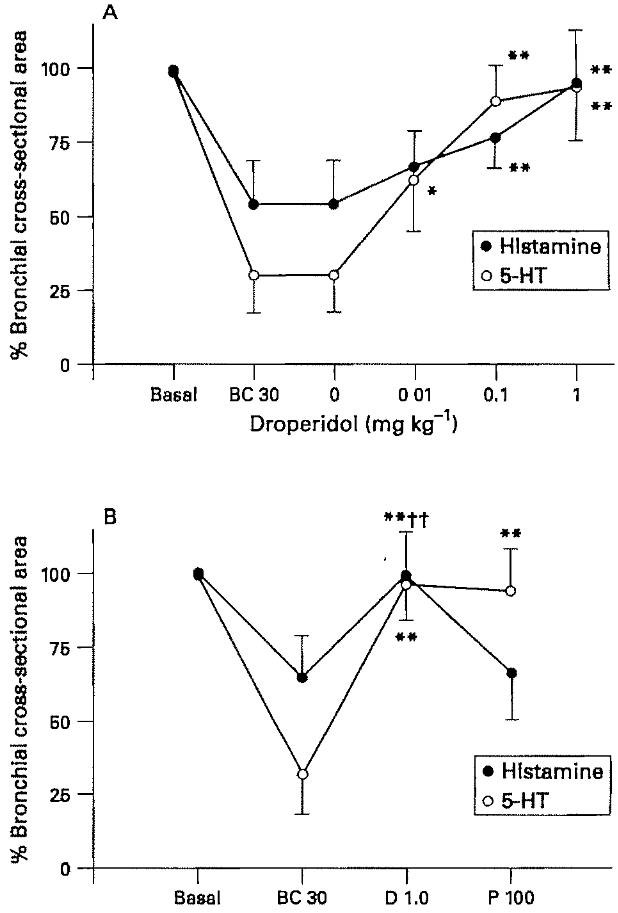

*Figure 1* Spasmolytic effect of droperidol on histamine- or serotonin (5-HT)-induced bronchoconstriction measured as percentage bronchial cross-sectional area. A: Droperidol produced dose-dependent reversal of bronchoconstriction induced by histamine or 5-HT. B: Propranolol 100 μg $kg^{-1}$ (P 100) reversed the spasmolytic effect of droperidol 1.0 mg $kg^{-1}$ (D 1.0) in the histamine but not in the 5-HT group. Data are mean, SD ($n=7$). Basal=before the start of histamine or serotonin (5-HT) infusion, BC30=30 min after the start of bronchoconstrictor (BC: histamine or 5-HT) infusion. *$P<0.05$, **$P<0.01$ compared with BC30; ††$P<0.01$ compared with P 100.

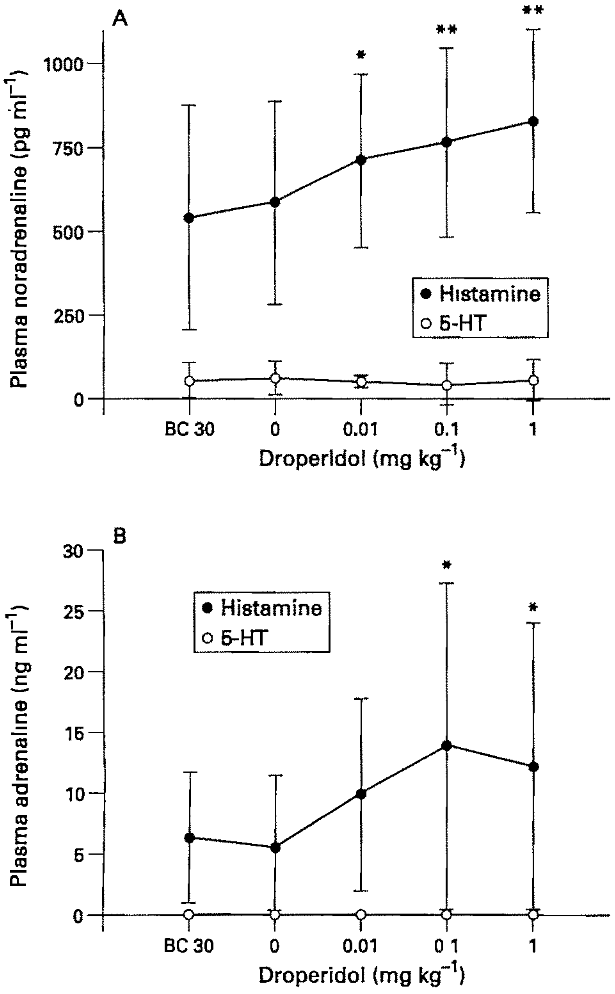

*Figure 2* Changes in plasma concentrations of noradrenaline (A) and adrenaline (B). BC30=30 min after the start of bronchoconstrictor (histamine or serotonin (5-HT)) infusion. Data are mean, SD ($n$=7). *$P$<0.05, **$P$<0.01 compared with BC30.

1.0 mg $kg^{-1}$ reversed 5-HT-induced decrease in bronchial cross-sectional area in both the 5-HT–droperidol (fig. 1A) and the 5-HT–droperidol–propranolol groups (fig. 1B). However, there were no significant changes in plasma adrenaline and noradrenaline concentrations, which were significantly lower than those in the histamine–droperidol group (fig. 2). Propranolol had no effect on droperidol-induced bronchodilatation (fig. 1B). The $ED_{50}$ for droperidol reversal of 5-HT-induced bronchoconstriction was 0.013 (0.011) mg $kg^{-1}$. Droperidol was significantly more potent at reversing 5-HT than histamine-induced constriction ($P$<0.01).

## Discussion

We have reported previously that droperidol inhibits histamine- and 5-HT-induced contraction of guinea pig tracheal smooth muscle *in vitro*.[6] Our study has confirmed that droperidol was capable of producing bronchodilatation in bronchospastic states induced by histamine or 5-HT *in vivo*. The mechanism of droperidol-induced relaxation may be via α-adrenoceptor block,[1] β-adrenergic stimulation by catecholamine release[2 3] and 5-HT receptor antagonism.[4–6] However, our previous *in vitro* study[6] indicated that prazosine (α-blocker) did not alter either 5-HT-induced tracheal contraction or the relaxant effect of droperidol. None the less, α-adrenoceptor block cannot be excluded as the α-adrenoceptor is involved in the mechanism of asthma.[12 13] Droperidol has been reported to induce catecholamine release.[2 3] In our study, the histamine groups indicated that droperidol produced a spasmolytic effect accompanied by catecholamine release and that propranolol completely antagonized droperidol-induced relaxation. Therefore, it is likely that catecholamine release is involved indirectly in droperidol-mediated relaxation. In contrast, in the 5-HT groups, droperidol-induced relaxation of 5-HT-induced bronchoconstriction was not caused by catecholamine release. Relaxation may be produced by a direct 5-HT receptor blocking action of droperidol. In agreement with our previous *in vitro* study,[6] in this study we found that the $ED_{50}$ of droperidol against 5-HT was one order of magnitude more potent than against histamine. These findings suggest that 5-HT-induced bronchoconstriction is more specifically antagonized by droperidol than histamine.

Gentil and colleagues found that droperidol prevented 5-HT- but not histamine-induced constriction but this was assessed indirectly using respiratory conductance.[4] However, Brown and colleagues[7 8] reported that indirect assessment of airway calibre by airway resistance and pulmonary compliance may be a less reliable assessment of bronchodilatation compared with direct vision using high resolution computed topography. We have also found that our direct vision method using a superfine fibreoptic bronchoscope was more sensitive than indirect measures.[10]

## Summary

In this study, we report the development and accuracy of a direct technique to measure airway calibre using a superfine fibreoptic bronchoscope. Ten mongrel dogs were anaesthetized with pentobarbitone and the trachea intubated with a tracheal tube; the small lumen of the tube allowed passage of a superfine fibreoptic bronchoscope (od 2.2 mm). Bronchial cross-sectional area and airway pressure were recorded continuously and dynamic pulmonary compliance and airway resistance calculated. The dogs were allocated to one of two groups. In the first group (six dogs), bronchoconstriction was induced with histamine 10 $\mu$g kg$^{-1}$ i.v. and 500 $\mu$g kg$^{-1}$ h$^{-1}$ c.i.v. Thirty minutes later, adrenaline 0–0.4 mg kg$^{-1}$ was given i.v. Bronchial cross-sectional area, dynamic pulmonary compliance and airway resistance were assessed simultaneously. In the second group, 0.9% saline was given 30 min after placement of the superfine fibreoptic bronchoscope and 10 min later atropine 0.1 $\mu$g kg$^{-1}$ was administered. In the first group, histamine decreased mean percentage bronchial cross-sectional area by 49.2 (SD 11.5) %, reduced dynamic pulmonary compliance from 32.1 (12.6) to 22.3 (5.2) ml cm $H_2O^{-1}$ and increased airway resistance from 39.1 (11.6) to 57.2 (10.2) cm $H_2O$ litre$^{-1}$ s$^{-1}$. Adrenaline produced a dose-dependent increase in percentage bronchial cross-sectional area and dynamic pulmonary compliance to 119.4 (31.3) % and 27.4 (5.5) ml cm $H_2O^{-1}$, respectively, and a decrease in airway resistance to 43.9 (7.2) cm $H_2O$ litre$^{-1}$ s$^{-1}$. There were significant correlations between percentage bronchial cross-sectional area and dynamic pulmonary compliance ($r$=0.720, $P$<0.0001) and airway resistance ($r$=0.727, $P$<0.0001). Atropine 0.1 mg kg$^{-1}$ increased basal bronchial cross-sectional area to 137.5 (16.9) %. These data indicate that adrenaline reversed histamine- and pentobarbitone-induced bronchoconstriction. (*Br. J. Anaesth.* 1997; **78**: 583–585).

**Key words**
Lung, bronchus. Equipment, bronchoscopes. Airway, calibre.

Airway calibre is influenced by several factors, including smooth muscle tone, oedema of the airway wall and airway secretory activity.[1] Airway calibre is normally assessed indirectly by measuring airway resistance or compliance, and these can be influenced strongly by airway secretions.[2] Moreover, several articles have noted the relative insensitivity of indirect measurements of airway calibre.[3–5] Brown and colleagues developed a technique for direct measurement of airway calibre using high-resolution computed tomography and showed that changes in airway calibre were not always accompanied by changes in total pulmonary resistance.[4] While their direct method appeared more specific than conventional indirect measures of airway calibre, the system is too large to use conveniently as an airway monitor in the operating theatre or in the intensive care unit. In this study, we report the development of a new portable direct method to quantify bronchial calibre using a superfine fibreoptic bronchoscope.

## Methods and results

After obtaining approval from our Animal Care Committee, 10 mongrel dogs (8–12 kg) were anaesthetized with pentobarbitone 30 mg kg$^{-1}$ i.v. and paralysed with pancuronium 200 $\mu$g kg$^{-1}$ h$^{-1}$ d.i.v. The trachea was intubated with a special tracheal tube (internal diameter 7.0 mm; Fuji system, Tokyo) with a small lumen into which a superfine fibreoptic bronchoscope (outer diameter 2.2 mm; OES Angiofiberscope AF type 22A, Olympus, Tokyo, Japan) could be inserted. With the tip of the fibrescope located between the second and third bifurcation of the right lung, bronchial cross-sectional area was monitored continuously. In addition, a pulmonary arterial catheter was inserted via the femoral vein to allow infusion of lactate Ringer's solution at 4 ml kg$^{-1}$ h$^{-1}$ and for drug administration. Systemic arterial pressure was monitored directly via the femoral artery.

### AIRWAY ANALYSIS

The lungs were ventilated with a respirator

(Newport ventilator model E-200, Tokibo, Tokyo, Japan) set as follows: $F\text{I}_{\text{O}_2} = 1.0$, controlled mechanical ventilation, ventilatory frequency 10 bpm, I:E ratio 1:1 and end-inspiratory plateau time 0.9 s, and constant inspiratory flow was adjusted to maintain an end-tidal carbon dioxide concentration of 4.5–5.0%. Airway pressure was recorded continuously to calculate dynamic pulmonary compliance and airway resistance. Dynamic pulmonary compliance and airway resistance are reported as the mean value of three consecutive breaths. Bronchial cross-sectional area (as seen by the bronchoscope) at the second–third bifurcation was monitored continuously. The bronchial cross-sectional area image on the monitor was printed via a videoprinter (Videoprinter VY-170, Hitachi, Tokyo, Japan) and measured using image analysis software (NIH image program which is well established and used widely; written by Wayne Rasband at the US National Institutes of Health and available from the Internet by anonymous ftp from zippy. nimh. nih. gov. or on floppy disk from NTIS, 5285 Port Royal Rd., Springfield, VA 22161, part number PB93-504868).

The dogs were allocated to one of two groups: adrenaline–histamine group ($n$=6) and atropine group ($n$=4). In the adrenaline–histamine group, bronchoconstriction was induced with histamine 10 μg kg$^{-1}$ i.v. followed by infusion of 500 μg kg$^{-1}$ h$^{-1}$ via the pulmonary arterial catheter. Systolic arterial pressure was maintained greater than 80 mm Hg with fluid (lactate Ringer's solution 50 ml kg$^{-1}$) and with continuous infusion of phenylephrine 0.5–2.0 μg kg$^{-1}$ min$^{-1}$, the rate being dependent on systolic arterial pressure. Thirty minutes later, when stable bronchoconstriction was achieved, adrenaline was given i.v.: 0 (0.9% saline), 0.05, 0.1, 0.2 and 0.4 μg kg$^{-1}$. The first measurement of dynamic pulmonary compliance and airway resistance was performed before insertion of the fibrescope. Bronchial cross-sectional area, dynamic pulmonary compliance and airway resistance were measured before and 30 min after the start of infusion of histamine and 1 min after each dose of adrenaline. At least 5 min elapsed between each dose of adrenaline. Measured bronchial cross-sectional area, dynamic pulmonary compliance and airway resistance were also expressed as a ratio of basal values (percentage bronchial cross-sectional area, percentage dynamic pulmonary compliance and percentage airway resistance, respectively). In the atropine group, bronchoconstriction was not induced. Thirty minutes after fixation of the bronchoscope, 0.9% saline and 10 min later atropine 0.1 mg kg$^{-1}$ were administered i.v. Only bronchial cross-sectional area was measured before and 5 min after saline and atropine to determine if pentobarbitone anaesthesia reduced bronchial calibre, as seen with thiopentone anaesthesia.[5]

## DATA ANALYSIS

All data are expressed as mean (SD). The correlations between percentage bronchial cross-sectional area and percentage dynamic pulmonary compliance and between percentage bronchial cross-sectional area and percentage airway resistance were calculated by computer assisted curve fitting (Graphpad-Prism). Data were analysed by repeated-measures ANOVA followed by the Scheffé $F$ test. $P<0.05$ was considered significant.

In the adrenaline–histamine group, fibrescope insertion produced no significant change in airway resistance (40.0 (12.4) to 39.1 (11.6) cm $H_2O$ litre$^{-1}$ s$^{-1}$) or dynamic pulmonary compliance (32.0 (12.5) to 32.1 (12.6) ml cm $H_2O^{-1}$). Histamine decreased percentage bronchial cross-sectional area by 49.2 (11.5) %, reduced dynamic pulmonary compliance from 32.1 (12.6) to 22.3 (5.2) ml cm $H_2O^{-1}$ (percentage dynamic pulmonary compliance by 25.2 (7.8) %) and increased airway resistance from 39.1 (11.6) to 57.2 (10.2) cm $H_2O$ litre$^{-1}$ s$^{-1}$ (percentage airway resistance to 153.4 (12.7) %). Adrenaline produced a dose-dependent increase in percentage bronchial cross-sectional area and percentage dynamic pulmonary compliance and a decrease in percentage airway resistance (fig. 1A). There was a significant correlation (fig. 1B) between percentage bronchial cross-sectional area and percentage

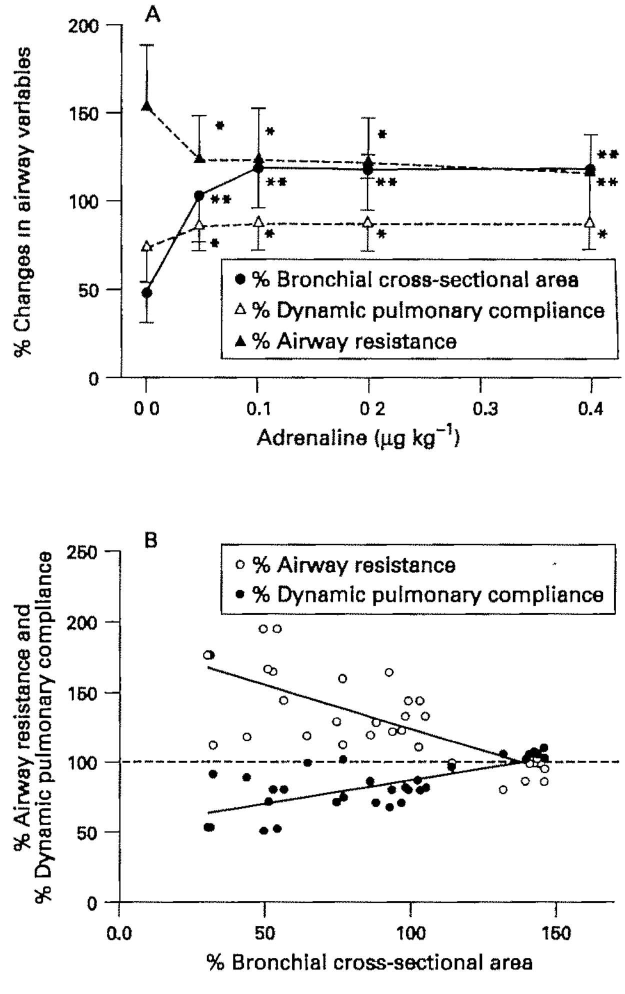

*Figure 1* A: Bronchoconstriction induced by infusion of histamine 10 μg kg$^{-1}$ i.v. and 500 μg kg$^{-1}$ h$^{-1}$. Changes in percentage bronchial cross-sectional area, percentage airway resistance and percentage dynamic pulmonary compliance. Data are mean, SD ($n$=6). $^*P<0.05$, $^{**}P<0.01$ compared with adrenaline 0 μg kg$^{-1}$. B: Correlation between percentage bronchial cross-sectional area and percentage dynamic pulmonary compliance ($r$=0.720, $P<0.0001$) and percentage airway resistance ($r$=0.727, $P<0.0001$).

dynamic pulmonary compliance ($r$=0.720, $P$<0.0001) and percentage bronchial cross-sectional area and percentage airway resistance ($r$=0.727, $P$<0.0001). When these correlations were analysed separately for each subject, the correlation was improved ($r$=0.889 (0.021) and $r$=0.906 (0.044), respectively). In the atropine group, atropine 0.1 mg $kg^{-1}$ produced a significant increase in basal bronchial cross-sectional area to 137.5 (13.8) % ($P$<0.05) compared with bronchial cross-sectional area after administration of 0.9% saline (100.7 (9.8) %).

## Comment

In this study we have reported a new direct method for assessment of airway calibre using a superfine fibreoptic bronchoscope and compared this with conventional indirect measures of dynamic pulmonary compliance and airway resistance. We reported a good correlation between percentage bronchial cross-sectional area, percentage dynamic pulmonary compliance and percentage airway resistance and suggest that our method provided simple, accurate and direct measurement of airway calibre. Calculation of dynamic pulmonary compliance and airway resistance requires airway pressure and pressure gradient measurements, which are dependent on airway smooth muscle tone, presence of oedema, secretion and airflow rate and pattern. Histamine-induced bronchoconstriction, used in this study, produces not only airway smooth muscle contraction and oedema but also an increase in airway secretion[6] which would strongly affect airway pressure measurements but have little effect on airway calibre. Therefore, dynamic pulmonary compliance and airway resistance do not accurately reflect airway calibre.

In support of this notion Brown and colleagues,[4] using high resolution computed tomography, reported that changes in airway calibre did not always follow changes in total pulmonary resistance. Our data also suggested that direct assessment of airway calibre using a superfine fibreoptic bronchoscope was more sensitive than dynamic pulmonary compliance and airway resistance. In histamine preconstricted airways, adrenaline produced greater bronchodilatation than that observed before histamine administration when assessing percentage bronchial cross-sectional area, yet percentage dynamic pulmonary compliance and percentage airway resistance did not completely return to pre-histamine values. These finding were not unexpected. As described above, infusion of histamine increases not only airway smooth muscle tone but also airway secretion. Even if adrenaline completely reversed smooth muscle contraction, airway secretions cannot be excluded. Therefore, dynamic pulmonary compliance and airway resistance would not return fully to basal as airway secretions were not aspirated during the experiment. In addition, our data suggest that pentobarbitone anaesthesia may increase vagal tone to reduce airway calibre as atropine increased basal bronchial cross-sectional area to approximately 140%. Similar data have been reported by Brown and colleagues[5] for thiopentone where atropine 0.2 mg $kg^{-1}$ caused significant airway dilatation (151 (25) %).

In this study, phenylephrine (an $\alpha_1$-agonist) was given i.v. at 0.5–2.0 $\mu g\ kg^{-1}\ min^{-1}$ to maintain systolic arterial pressure greater than 80 mm Hg. When the effect of phenylephrine on histamine-induced bronchoconstriction in dogs ($n$=6) was studied previously, we found that phenylephrine 100 $\mu g\ kg^{-1}$ significantly increased histamine bronchoconstriction while phenylephrine 1.0 and 10 $\mu g\ kg^{-1}$ did not (unpublished data). Therefore, the dose of phenylephrine we used did not significantly affect histamine-induced bronchoconstriction.

# Cardiovascular effects of an intubating dose of rocuronium 0.6 mg $kg^{-1}$ in anaesthetized patients, paralysed with vecuronium

J. M. K. H. WIERDA, M. SCHURINGA AND L. VAN DEN BROEK

## Summary

We have studied, in adult patients, ASA I–II, the cardiovascular effects of an intubating dose of rocuronium 0.6 mg $kg^{-1}$. After induction, patients were paralysed with vecuronium and the trachea intubated. Heart rate (HR) and non-invasive mean arterial pressure (MAP) were measured every 1 min. After stabilization of HR and MAP, defined as <3% change over three measurements, rocuronium ($n$=20) or saline ($n$=10) was injected at random. Mean HR increased initially from 66.6 to 72.1 beat $min^{-1}$, 4 min after rocuronium, and then decreased gradually to 69.6 beat $min^{-1}$, that is a net increase of 3.3 beat $min^{-1}$ over 10 min ($P$<0.001), whereas after saline there was a gradual decrease from 65.8 to 60.9 beat $min^{-1}$ ($P$<0.001) over 10 min. From the third minute, HR was significantly higher in the rocuronium group. Mean MAP decreased in both groups within 10 min to a similar extent after rocuronium and saline, that is from 74.9 to 72.1 mm Hg and from 74.7 to 72.2 mm Hg, respectively (both $P$<0.001). There were no differences in MAP at any time between the rocuronium and saline groups. We conclude that an intubating dose of rocuronium, in the absence of haemodynamic effects related to paralysis itself, resulted in a limited increase in HR without change in MAP, probably because of its weak vagolytic activity. (*Br. J. Anaesth.* 1997; **78**: 586–587).

**Key words**
Neuromuscular block, rocuronium. Neuromuscular block, vecuronium. Cardiovascular system, effects. Intubation tracheal.

Rocuronium is a steroidal non-depolarizing neuromuscular blocking agent with a time course similar to that of vecuronium, but with a faster onset of action. In the cat, rocuronium has a lower vagal: neuromuscular blocking ratio than vecuronium,[1] which may be (partly) responsible for the haemodynamic effects reported in humans.[2–4] An indirect, relaxation-induced reduction in preload caused by abdominal pooling may also contribute to the haemodynamic effects of neuromuscular blocking agents. We studied the cardiovascular effects of an intubating dose of rocuronium in anaesthetized, paralysed patients, to exclude interference from neuromuscular block-induced haemodynamic effects.

## Methods and results

After approval of the local Ethics Committee and with informed consent, we studied 30 ASA I–II patients (aged 18–65 yr), undergoing elective surgery. Patients with neuromuscular or cardiovascular disease and those receiving any potentially interacting medication were excluded. After premedication with oral midazolam 0.1–0.15 mg $kg^{-1}$, anaesthesia was induced with thiopentone 4–6 mg $kg^{-1}$ i.v. and fentanyl 1–3 μg $kg^{-1}$ i.v., and maintained with 1% end- tidal isoflurane concentration and 65% nitrous oxide in oxygen. Tracheal intubation was performed 3 min after vecuronium 70 μg $kg^{-1}$. Heart rate (HR) and mean arterial pressure (MAP) were monitored non-invasively from induction at 1-min intervals. Oxygen saturation was measured continuously, end-expiratory carbon dioxide was maintained at 4.0–4.5 kPa and neuromuscular block was monitored by accelerometry (train-of-four ratio, TOF-Guard). After stabilization of HR and MAP, a bolus of rocuronium 0.6 mg $kg^{-1}$ ($n$=20) or 0.9% saline ($n$=10) was administered over 10 s into a forearm vein according to a randomization scheme. Stability was assumed if <3% change in HR and MAP had occurred over the last three measurements. Measurements were continued for 10 min in the absence of surgical stimulation and HR and MAP were compared within each group (ANOVA for multiple measurements) and between groups (Student's $t$ test for independent samples).

All patients were classified as ASA I. Groups (rocuronium *vs* control) were comparable in age (mean 37.5 (range 20–63) *vs* 34.5 (25–56) yr), height (mean 179 (SD 10) *vs* 178 (7) cm), weight (76.5 (10.3) *vs* 76.1 (10.5) kg) and sex distribution (M/F: 15/5 *vs* 6/4). The interval between intubation and stabilization was 12–16 min. At the time of administration of rocuronium or saline, all patients showed >95% neuromuscular block.

HR and MAP values were similar in both groups

immediately before administration of rocuronium or saline (table 1). After rocuronium, HR increased significantly ($P<0.001$), whereas after saline a limited, but statistically significant decrease in HR occurred ($P<0.001$). In both groups MAP decreased with time to the same small extent ($P<0.001$). After rocuronium, HR was significantly higher than after saline over the interval from 3 to 10 min, whereas MAP did not differ between the groups (see table 1 for *P* values). At the end of the study all patients in the rocuronium group showed complete block whereas twitch height depression in the saline group was still 93.9 (4.1)%.

## Comment

Although rocuronium has a relatively low vagal:neuromuscular blocking ratio in animals compared with vecuronium,[1] it did not show clinically relevant haemodynamic effects in a dose range up to $3\times ED_{90}$ in humans.[3 4] Our results in paralysed patients are in agreement with earlier findings for the same dose in non-paralysed patients.[3] In contrast, Booth and colleagues[2] found more significant increases (>30%) in HR in humans after a similar dose of rocuronium. However, in the latter study hyoscine, a vagolytic agent, which was given as premedication, may have enhanced the slight vagolytic effect of rocuronium, either by addition or synergism. A clinical study[5] in which these drugs were given in reverse order may support this assumption. Methyl-atropine induced a more pronounced vagolytic effect in the presence of high concentrations of rocuronium, compared with low concentrations. In another clinical study,[6] premedication with atropine i.m. was associated with a lower pre-induction HR, most probably because of vagomimetic activity associated with small doses of atropine. This vagomimetic action disappeared after induction of anaesthesia, resulting in a more pronounced increase in HR in patients premedicated with atropine. These findings[5 6] support the likelihood of a drug interaction being the explanation for the different increases in HR in the current study and in that of Booth and colleagues.[2]

# Changes in extracellular brain ascorbate in rat striatum in response to administration of non-volatile anaesthetic agents

M. MIELE AND M. FILLENZ

## Summary

We used constant potential *in vivo* voltammetry to measure changes in striatal ascorbate in the rat in response to i.p. administration of several non-volatile anaesthetics. Propofol and pentobarbitone, which enhance GABA-mediated neuronal inhibitions, decreased ascorbate current to 27.0 (SEM 7.4) % and 46 (6) % of control, respectively. Chloral hydrate, diazepam alone or with ketamine, and fentanyl–fluanisone with midazolam produced no changes in ascorbate current. (*Br. J. Anaesth.* 1997; **78**: 588–590).

**Key words**
Brain, ascorbate. Anaesthetics i.v. Hypnotics benzodiazepine. Rat. Measurement techniques, voltammetry.

*In vivo* voltammetry has been used extensively to monitor extracellular ascorbate in the brain. The extracellular concentration of ascorbate is 416±66 μmol litre$^{-1}$.[1] There is evidence from several different approaches that changes in neuronal activity are accompanied by changes in the extracellular concentration of ascorbate. There is extensive evidence that increased activity of glutamatergic pathways is accompanied by release of ascorbate.[2]

In this study we have used *in vivo* voltammetry to monitor changes in extracellular ascorbate in the rat striatum in response to i.p. administration of various non-volatile anaesthetic agents in order to test the hypothesis that extracellular ascorbate could be used as an index of the level of neuronal activity.

## Methods and results

A carbon paste electrode was implanted stereotactically in the right striatum of male Sprague–Dawley rats (200 and 300 g) under anaesthesia. Extracellular brain ascorbate was measured using constant potential voltammetry.[3] Experiments were performed 24 h after electrode implantation. Anaesthesia was assessed using palpebral, corneal and withdrawal reflexes. Muscle tone was evaluated by assessing resistance to flexion or extension of the limbs.

Results are given as mean (SEM); *n*=number of observations. Data were compared by Students's *t* test using absolute values.

Basal ascorbate current values were 0.89 (0.80) nA (*n*=21) (range 0.3–1.3 nA). After i.p. injection of saline there was a rapid increase in ascorbate, which returned to control values within 5–10 min (fig. 1A).

Two rats were given propofol 25 mg kg$^{-1}$ i.p. The rats were deeply sedated rather than fully anaesthetized for 45 (2.5) min. Transition from sedation to full recovery was slow. Sedation was accompanied by a decrease to 73.0 (7.4) % (*P*=0.038, *n*=8) of basal ascorbate current (fig. 1B) which showed slow recovery and reached basal values only when animals had recovered fully and resumed their normal behaviour.

Sodium pentobarbitone 40 mg kg$^{-1}$ was given i.p. to three rats. Rats were deeply anaesthetized for 91 (4) min and emerged from anaesthesia very slowly. During anaesthesia the ascorbate current decreased gradually to 54 (6.1) % from a baseline current of 0.84 (0.23) nA (*P*=0.0034, *n*=6) (fig. 1C). The decrease in ascorbate produced by sodium pentobarbitone was significantly greater than that produced by propofol (*P*=0.05, Mann–Whitney *U* test).

Chloral hydrate 400 mg kg$^{-1}$ was given i.p. to two rats. Duration of anaesthesia was 107 (7) min, from which rats emerged rapidly and with little warning. There was no change in ascorbate current throughout the period of anaesthesia (fig. 1D). Fluctuations related to motor activity reappeared when animals were recovered fully and resumed their normal behaviour.

Diazepam 5 mg kg$^{-1}$ was administered i.p. to two rats. The animals remained still and sedated for 20–30 min. Basal ascorbate current remained constant throughout the experiment.

A mixture of fentanyl 0.25 mg kg$^{-1}$–fluanisone 0.8 mg kg$^{-1}$ and midazolam 0.4 mg kg$^{-1}$ produced anaesthesia of 35 (5) min duration with no change in ascorbate current throughout the period of anaesthesia.

Ketamine 100 mg kg$^{-1}$ mixed with diazepam 5 mg kg$^{-1}$ was given i.p. to three rats. Duration of anaesthesia was 28 (1.8) min (*n*=5). There were no significant changes in ascorbate current during ketamine–diazepam anaesthesia.

## Comment

The results of our experiments, designed to test the hypothesis that extracellular ascorbate could be used as an index of the level of neuronal activity, showed only a partial correlation between reduction in ascorbate current and depth of anaesthesia. Although all drugs produced a significant reduction in behavioural activity and reflex responses, only propofol and pentobarbitone produced a reduction in ascorbate current. These differences are probably a result of different mechanisms of action, although all non-volatile anaesthetic agents reduce the cerebral metabolic demand for oxygen and depress electrophysiological activity. Most anaesthetics either enhance inhibition or depress excitation by interacting with receptors for GABA, glutamate or opioid peptides. A strong correlation exists between drug potency as modulators of the GABA$_A$ receptor and anaesthetic potency *in vivo*.[4]

Propofol and pentobarbitone are lipophilic compounds and act on the GABA$_A$ receptor at a site distinct from that of benzodiazepines, enhancing GABA-mediated transmission.[5] Unlike barbiturates, the benzodiazepines diazepam and midazolam do not directly gate the Cl$^-$ channels of GABA$_A$ receptors but require GABA to express their effects. Voltammetric measurement of ascorbate in a previous study showed that an anxiolytic dose (3 mg kg$^{-1}$) of diazepam had no effect on basal ascorbate current but reduced the stimulated increase in ascorbate.[6] This suggests a different origin for basal and stimulated ascorbate.

Fentanyl mimics the action of opioid peptides acting selectively on μ opioid receptors, which blunt or eliminate responses to noxious stimuli. In microdialysis experiments, fentanyl was found to produce no change in the concentration of glutamate in striatal dialysate (unpublished).

The dissociative anaesthetic ketamine acts on glutamatergic NMDA receptors producing a state of sedation, immobility, amnesia and marked analgesia.

The results of this study suggest that anaesthetic agents which enhance GABA-mediated inhibition of neuronal activity produced a reduction in ascorbate. Although chloral hydrate shares the same mechanism of action as pentobarbitone and propofol, the increase in regional cerebral blood flow and dopamine implies that it produced some neuronal activation.

CASE REPORT

# Conservative management of extradural abscess complicating spinal–extradural anaesthesia for Caesarean section

R. H. DYSART AND V. BALAKRISHNAN

## Summary

We report a case of lumbar extradural abscess that presented 9 days after an elective Caesarean section performed under combined spinal–extradural anaesthesia. This was successfully treated conservatively with full recovery. The clinical course included development, and then resolution, of mild paraparesis. Conservative treatment of an extradural abscess in the obstetric population has not been described previously. (*Br. J. Anaesth.* 1997; **78**: 591–593).

**Key words**
Anaesthesia, obstetric. Anaesthetic techniques, extradural. Anaesthetic techniques, subarachnoid. Complications, extradural abscess.

## Case report

A 26-yr old, 55-kg, para 0, gravida 2 woman presented at 39 weeks' gestation for elective Caesarean section. Indications for surgery were cephalopelvic disproportion and mild pre-eclampsia. A full coagulation screen was not requested as the preoperative platelet count was normal ($178 \times 10^9$ litre$^{-1}$). The obstetric anaesthetic registrar on duty used a combined 16-gauge extradural–spinal pack and 0.5% heavy bupivacaine 3 ml was injected at L3–4 using a 26-gauge pencil point needle; an extradural catheter was then inserted for postoperative pain relief. A routine aseptic technique was used, including gloves, gown, mask, chlorhexidine skin preparation and drapes. Surgery was uneventful and a healthy baby was born with Apgar scores of 9 and 9. No antibiotic prophylaxis was used. At the end of surgery it was noted that blood could be aspirated from the extradural catheter, and therefore the registrar removed it and uneventfully reinserted a new one in a higher space at L2–3. This catheter was used after operation for intermittent top-up doses of extradural pethidine 50 mg in 10 ml saline, administered by the midwife, which was our routine at that time. There was an uneventful postoperative course, the catheter was removed at 48 h (after 13 doses of extradural pethidine), and mother and baby were discharged home after 6 days. There was nothing unusual about the nature of mother's postoperative pain, and she received diclofenac 75 mg once or twice daily while in hospital, and occasional paracetamol.

Late in the evening, 9 days after operation, the woman was readmitted with increasing backache, pyrexia (39.3 °C), white cell count $15.5 \times 10^9$ litre$^{-1}$, erythrocyte sedimentation rate 133 mm h$^{-1}$ and tenderness over the extradural site. There were no signs of endometritis and neurological examination was normal, except for restricted straight leg raising to 70°. She was given opioid analgesia overnight which was effective.

On the following morning she was still pyrexial (39.3 °C) and feeling unwell, with headache and shivering. Her sensation, power and reflexes were still normal, and ceftriaxone, gentamicin and metronidazole were prescribed. After consultation with anaesthetic staff a neurosurgical opinion was obtained. An extradural infection was suspected and conservative treatment was recommended as the patient had no focal neurological signs.

During this 10th day there was worsening of back pain, with pain radiation down both lower limbs, neck pain and headache. PCA morphine was commenced. In the evening she started to develop a vague numb feeling in her right leg, and mild weakness of the left leg. Because of severe back pain when mounting a bedpan, an indwelling catheter was inserted for comfort. Late that evening she felt slightly better with easing of her headache. She had MRC grade 4/5 weakness of ankle flexion on both sides, but there was no impairment of sensation or reflex changes.

The next morning (11 days after operation) she was still pyrexial (39.6 °C) and unwell, with a tachycardia occasionally approaching 150 beat min$^{-1}$. Sensation in her legs was now variable, with patchy numbness to pinprick. Blood cultures obtained on the evening of readmission now revealed gram-positive *Staphylococcus*. At midday she felt reasonably well with a supple neck but with reduced power in all leg muscle groups (4/5) but especially reduced knee extension (1/5). She was photophobic and felt "heavy" in her legs.

The neurosurgeon now considered an MRI scan was indicated because of the neurological signs and

R. H. DYSART, MB, CHB, FANZCA, V. BALAKRISHNAN, MS, FRACS, Wellington Hospital, Capital Coast Health Ltd, Riddiford St, Private Bag 7902, Wellington South, New Zealand Accepted for publication: January 3, 1997.

difficulty in determining how much power and sensation changes were caused by high consumption of PCA morphine. Spinal MRI scan demonstrated a lesion posteriorly at L2–3 which was 2.4×1.2 cm. T1- and T2-weighted images suggested space occupying fluid collection and not old bleeding or fibrosis. The extent and loculation of the lesion, together with the clinical findings, supported a diagnosis of extradural abscess.

Although spinal surgery was considered, it was not performed as there was subjective improvement and reasonably mild neurological signs. At this stage she had foot drop and weakness of ankle inversion/eversion, with no detectable ankle reflexes. There was reduced sensation to pinprick from the L5 dermatome to the perianal region.

From this point on she maintained gradual improvement in her clinical state. On day 12 after operation she again felt slightly improved, with no headache and lessening backache. Her blood cultures confirmed *Staphylococcus aureus*, and the antibiotic regimen was changed to flucloxacillin and rifampicin.

Over the next 2 weeks she continued to improve steadily, mobilizing slowly from day 15 after operation and was afebrile on day 17. Morphine PCA was discontinued on day 18 and on day 20 neurological signs had almost returned to normal apart from altered sensation on the soles of her feet. She still had occasional shooting pains in her thighs and calves, and absent ankle reflexes. She was discharged home on day 25 with a 6-week course of oral flucloxacillin, and ongoing physiotherapy.

One month later she had made a full neurological recovery apart from slight L5 numbness on the right, with normal power and reflexes in her lower limbs. She had no further backache and straight leg raising improved to 90°.

## Discussion

In the recent literature there has been an increase in reported extradural infections associated with extradural anaesthesia.[1–5] However, it is not clear if this represents a real increase in incidence (to accompany the more widespread use of extradural anaesthesia) or merely an increase in reporting. This report represents the second case of extradural abscess after extradural anaesthesia in obstetrics at our institution (see NganKee and colleagues[1]) and has led to cessation of our previous policy of intermittent bolus pethidine top-ups by midwives for analgesia after Caesarean section. We were concerned with frequent accessing of the extradural filter for top-ups (up to 14 doses of extradural pethidine often being used), and thus catheters are now removed at the end of surgery after extradural administration of morphine.

The justification for resiting an extradural after completion of Caesarean section for postoperative pain relief may be debated. However, this was occasionally performed at our institution at that time because of postnatal ward staff request as they were so impressed with the analgesia and earlier mobilization it allowed. We are presently looking at reintroducing extradural pethidine for postoperative Caesarean analgesia in a closed sterile patient-controlled extradural analgesic system.

Most reported extradural abscesses have been unrelated to anaesthesia and are associated with older age, immunocompromise, infection, i.v. drug abuse and trauma.[6–10] Magnetic resonance imaging with contrast enhancement is now the diagnostic tool of choice.[11] There is no agreed *management* of choice. Most authors describe surgical drainage and antibiotic treatment.[2 4 7–10] Percutaneous drainage under x-ray control with irrigation has also been described, although this involves the risk of spread of infection.[12] Others have advocated medical treatment in selected patients[6 11 13] (e.g Leys and colleagues[6]: poor surgical risk; extensive abscess along the vertebral canal; minimal or no neurological deficit; complete paralysis >3 days). Del Curling, Gower and McWhorter[7] found that lumbar abscesses did surprisingly well, usually with full neurological recovery (managed with both operative debridement and antibiotics).

There are no studies to recommend one management in comparison with another. The nature of the condition and the small numbers affected does not readily permit a controlled study of therapies. The variable rate of progression of neurological symptoms after presentation of an extradural abscess makes many neurosurgeons uneasy about conservative treatment. Some cases have had precipitous onset of neurological deficit, suggesting mechanical compression alone is not an adequate explanation. Thrombosis or phlebitis and oedema are probably implicated. It is not clear from the literature however if precipitous irreversible deterioration is a feature of lumbar abscess as it may be with thoracic or cervical abscess. Possibly the young, healthy, obstetric population is different and more amenable to conservative management, especially if the abscess is lumbar and neurological examination is normal or only mildly affected. The extradural space enlarges below L1 and an abscess here usually results in cauda equina syndrome rather than spinal cord compression. However, it is considered important to have the following factors present if pursuing medical management: bacteriological diagnosis, ready access to appropriate imaging, neurosurgical back-up and close clinical follow-up.

In summary, this case report described successful conservative management of extradural abscess in an obstetric patient. Such management has been reported previously in other groups of patients, but not in the obstetric population.

# KTP laser-resistant properties of the reinforced laryngeal mask airway

J. J. PANDIT, P. CHAMBERS AND S. O'MALLEY

## Summary

We have assessed, *in vitro*, the effect of KTP laser strike on the reinforced laryngeal mask airway (RLMA) under a variety of conditions. At power densities normally encountered in clinical practice, using a divergent KTP laser beam, the RLMA could not be penetrated and did not ignite with laser strike. The RLMA was penetrated at a high power density of 6.94 W $mm^{-2}$ after 45–60 s. A flame appeared over the RLMA shaft at this power density after 12–35 s. The black marker line on the RLMA shaft was somewhat more vulnerable to the effects of laser strike. The flow of oxygen and nitrous oxide within the shaft did not appreciably alter the laser-resistant properties of the RLMA. The RLMA cuff was more vulnerable to laser strike than was the shaft and was penetrated at very low power densities. Filling the cuff with saline had a protective effect and penetration did not occur at power densities which caused penetration of air-filled cuffs (0.37 W $mm^{-2}$). (*Br. J. Anaesth.* 1997; **78**: 594–600).

**Key words**
Equipment, lasers. Equipment, masks anaesthesia. Surgery, otolaryngological.

Laser surgery was introduced into otolaryngology in the early 1970s. Strong and Jako first used the carbon dioxide laser in laryngeal work.[1] Since then the use of the laser has become widespread. The carbon dioxide laser is delivered by a bulky articulated arm or by coupling to an operating microscope. These delivery methods limit the manoeuvrability and access to tissue that the surgeon can achieve.

The Nd:Yag laser (yttrium-aluminium-garnet treated with neodymium ions pumped with a krypton arc lamp) was introduced in the 1980s.[2] Its main advantage over the carbon dioxide laser is that it can be delivered by means of a more easily handled fibreoptic light cable. It has greater coagulative properties but less cutting ability than the carbon dioxide laser. Du Pont introduced the KTP laser in the 1980s. This laser uses an Nd:Yag laser to produce a beam at a wavelength of 1064 nm which is then passed through a potassium titanyl phosphate (KTP) crystal to produce visible green light at a wavelength of 532 nm.[2] This light can be transmitted through a fibreoptic cable, producing a divergent beam, or through an operating microscope producing a coherent (parallel) beam. A divergent beam diffuses its energy over a progressively wider area as it travels away from the source, whereas a parallel beam imparts its total energy over the same area whatever the distance of the source from the target. Therefore, parallel KTP or carbon dioxide laser beams impart much higher power densities to the tissues they strike than does the divergent KTP laser. The KTP laser cuts better and faster than the Nd:Yag and coagulates better than the carbon dioxide laser.[2 3] Tissues can therefore be cut, coagulated and vaporized with the same laser by varying power, exposure time and spot size. Unlike the Nd:Yag laser which needs an expensive shaped sapphire tip to produce good cutting, the KTP can achieve this using a bare fibre.

The KTP laser is now used extensively in ENT surgery for stapedectomy, tympanoplasty, reduction of turbinates and in functional endoscopic sinus surgery. Its greatest use is probably in oropharyngeal surgery in resecting tissue and in laryngeal work where its vaporizing properties are more useful.[3–5]

During laser surgery of the oral or laryngeal cavities, there is a serious risk of ignition of the tracheal tube.[6] To avoid laser fire, special anaesthetic techniques and tracheal tubes have been designed, and several studies have examined the laser-resistant properties of such tracheal tubes.[7–10]

Although the laryngeal mask airway (LMA) and the reinforced laryngeal mask airway (RLMA) are being used increasingly during laser surgery of the upper airway,[11] there have been relatively few reports of their laser-resistant properties. Brimacombe and co-workers have reported on the incendiary properties of the RLMA to carbon dioxide lasers[12 13] and found that it is resistant to penetration, ignition and combustion compared with PVC tracheal tubes.

To our knowledge, the incendiary characteristics of the RLMA to the KTP laser have not been studied previously. The main aim of this study was to assess if the RLMA is resistant *in vitro* to penetration and combustion using a divergent beam, at power densities normally encountered in our standard surgical practice. Second, we wished to determine the power density at which the RLMA would be penetrated or ignite.

## Materials and methods

### LASER SOURCE

A Laserscope KTP surgical laser system (Laserscope Inc, San Jose, CA, USA) was used to deliver the laser beam via a Laserscope Endostat optical delivery fibre (0.3 mm radius). This is a quartz thread covered by silicone cladding and a plastic–silicone jacket. The purpose of the cladding is to reflect light travelling within the fibre, and the jacket offers mechanical support. Before each experiment, the fibre was stripped and calibrated in accordance with the manufacturer's instructions. The power output at source of the Laserscope surgical delivery system could be varied between 0 and 20 W.

The laser beam is divergent around the fibre core at 15° (that is 7.5° each side of the core). The fibre radius is 0.3 mm, so the area of laser strike at a distance $d$ and thus the power density of the laser strike on the laryngeal mask is in accordance with equations (1–3) (personal communication, Rhys Llewellyn, European Marketing Manager, Laserscope):

$$\text{Power density (W mm}^{-2}) = \text{power output of laser at source (W) / area of laser strike (mm}^2) \quad (1)$$

$$\text{Area of laser strike} = \pi(0.3+x)^2 \quad (2)$$

$$x = d(\tan 7.5°) \quad (3)$$

Therefore, on contact of the fibre with the shaft, the area of laser strike is 0.28 mm$^2$; at a distance of 5 mm, the area is 2.88 mm$^2$.

### LARYNGEAL MASK AIRWAY

A set of RLMA (Intavent Ltd, Reading, UK) of standard dimensions were used: size 2.5, mean wall thickness 1.7 mm (range 1.55–1.85 mm; tolerance ±0.15 mm) and cuff wall thickness 0.55 mm (range 0.45–0.65 mm; tolerance ±0.1 mm). Each RLMA was labelled with its own identifying number (e.g. 031, 032, etc).

### EXPERIMENTAL DESIGN

Each procedure was conducted under the same experimental design. The RLMA was held steady by a metal clamp on a metal stand. Gas flow through the RLMA was provided by attaching it to a standard co-axial breathing system from a Boyle's machine. The laser-emitting fibre was held in place by a metal clamp on a second metal stand, allowing the distance ($d$) between the fibre and RLMA to be adjusted (eqn (3)). The laser beam was directed to the clear part of the shaft, between the metal rings. This was because the total area presented by the metal rings is relatively small and it was felt that under clinical conditions a laser would be more likely to involve the clear part of the tube. The metal rings were struck by the laser when the diameter of the area of laser strike exceeded the distance between the metal rings (i.e. greater than 1 mm). In each procedure, laser strike was continued either for a preset period of time (e.g. 20 s) or until an effect on the RLMA was seen. Video recordings of the experiments were made and any significant effects and the time at which they occurred were recorded.

The experimental procedures were designed to examine a sequence of questions.

### EXPERIMENTAL PROCEDURES

*Procedure A: at a power density normally encountered in standard practice, do different RLMA have similar laser-resistant characteristics?*

This was the control to establish that the supply of RLMA was homogeneous. The RLMA was held free-standing in room air not attached to the anaesthetic system. Using a laser source power output of 10 W, the fibre was held at a distance of 5 mm from the shaft (power density 3.47 W mm$^{-2}$). Laser strike was maintained continuously for 20 s. A total of seven separate tubes were used, and each tube was subjected to at least two exposures at this power density.

*Procedure B: what is the effect of increasing the power density by reducing the distance between the laser fibre tip and the RLMA shaft?*

RLMA were held free-standing in room air. A laser source power output of 10 W was selected and laser strike was maintained continuously for 20 s. Tests were conducted at distances between the RLMA and laser fibre of 5 mm (power density 3.47 W mm$^{-2}$), 3 mm (power density 6.57 W mm$^{-2}$), 2 mm (power density 10 W mm$^{-2}$) and with the fibre in contact with the RLMA (power density 35.7 W mm$^{-2}$).

*Procedure C: what is the effect if the laser strikes the radio-opaque black marker line on the RLMA shaft?*

The RLMA was held free-standing in room air. A laser source power output of 10 W was selected with the fibre at a distance of 5 mm from the shaft (power density 3.47 W mm$^{-2}$). Laser strike was maintained continuously for 20 s with the laser aimed at the black line on the RLMA shaft.

*Procedure D: does oxygen and nitrous oxide flow within the RLMA have any effect on the laser-resistant properties of the shaft?*

A laser source power output of 10 W was selected, the fibre at a distance of 5 mm from the RLMA shaft as in experimental procedure A (power density 3.47 W mm$^{-2}$). The RLMA was attached to the anaesthetic system with a flow of oxygen 2 litre min$^{-1}$ and nitrous oxide 4 litre min$^{-1}$. Laser strike was maintained continuously for 20 s.

*Procedure E: at what power density can the RLMA be penetrated or ignite?*

Three separate groups of experiments (E1, E2 and E3) were performed.

*Experiment E1 (effect of increasing power output at a fixed distance).* The RLMA was connected to the anaesthetic system with oxygen 2 litre min$^{-1}$ and nitrous oxide 4 litre min$^{1}$ flowing through it. The laser fibre was held at a distance of 5 mm from the shaft. Laser strike was continuous for up to 60 s. The effects of power outputs of 10 W (power density 3.47 W mm$^{-2}$), 15 W (power density 5.21 W mm$^{-2}$) and 20 W (power density 6.94 W mm$^{-2}$) were observed.

*Experiment E2 (effect of increasing power output with laser fibre in contact with RLMA).* The RLMA was connected to the anaesthetic system with oxygen 2 litre min$^{-1}$ and nitrous oxide 4 litre min$^{1}$ flowing through it. The laser fibre was held in contact with the RLMA shaft and laser strike was continuous until an effect was observed. The effects of power outputs of 10 W (power density 35.7 W mm$^{-2}$) and 20 W (power density 71.4 W mm$^{-2}$) were noted. The laser fibre was pushed through the damaged RLMA and 20 W of power reapplied with oxygen and nitrous oxide flowing through the system and RLMA shaft.

*Experiment E3 (effect of oxygen and air mix flowing through the RLMA).* The RLMA was connected to oxygen 2 litre min$^{-1}$ and air 4 litre min$^{-1}$ flowing through the anaesthetic system. The laser fibre was held in contact with the RLMA shaft and a power output of 20 W was applied (power density 71.4 W mm$^{-2}$). After 45 s the laser fibre was pushed through the damaged RLMA and the power output of 20 W was reapplied to assess the effects of laser within the oxygen and air gas stream.

### *Procedure F: what is the effect of the laser on the RLMA cuff filled with air?*

The RLMA was held in its clamp, free-standing in room air. The laser power output at source was set to 10 W. The RLMA cuff was filled with 12 ml of air, in accordance with the manufacturer's instructions. First, the laser fibre was held 10 mm from the cuff (power density 1.22 W mm$^{-2}$) and laser strike was continued for 20 s. Second, the laser fibre was held 20 mm from the cuff (power density 0.37 W mm$^{-2}$) and laser strike continued for 20 s. Third, the fibre was held 35 mm from the cuff (power density 0.13 W mm$^{-2}$) and laser strike was continued for 60 s. Finally, the fibre was held 40 mm from the cuff (power density 0.10 W mm$^{-2}$) and laser strike continued for 60 s.

### *Procedure G: what is the effect of the laser on the RLMA cuff filled with saline?*

The RLMA was held in its clamp, free-standing in room air. The laser power output at source was set to 10 W. The cuff was filled with 12 ml of saline. First, the laser fibre was held 10 mm from the cuff and laser strike continued for 20 s (power density 1.22 W mm$^{-2}$). Second, the fibre was held 20 mm from the cuff and laser strike continued for 60 s (power density 0.37 W mm$^{-2}$).

## Results

The result of procedure A was that there was no discernible effect of laser strike on the clear part of the shaft after continuous firing for 20 s.

In procedure B (table 1), there was no penetration of the shaft with the laser strike, even at relatively high power densities. At a power density of 10 W mm$^{-2}$ the surface silica layer gave a yellow–green "flare" within 7 s of being struck by the laser, a layer of silica ash then formed which seemed to prevent further penetration of the shaft by the laser beam. Higher power densities (35.7 W mm$^{-2}$) caused the surface to flare within 1 s: a flame then burned along the plastic sheath of the laser fibre, but there was no fire on the RLMA and after 20 s there was no penetration of the shaft.

In procedure C (table 2), at a power density (3.47 W mm$^{-2}$) which had no effect on the clear part of the

shaft (procedures A and B, table 1), laser strike on the black line caused an instant flare and after 20 s produced a crater filled with silica ash. This crater was similar to that produced at a power density of 10.0 W mm$^{-2}$ on the clear part of the shaft (table 1), but subjectively, was somewhat deeper. There was no penetration of the RLMA.

In procedure D (table 3), at a power density of 3.47 W mm$^{-2}$ (which had no effect in experimental procedures A and B), the flow of gases which support combustion within the tube did not change the laser-resistant properties of the shaft.

In procedure E (table 4), the RLMA shaft proved to be laser-resistant up to power densities of 5.21 W mm$^{-2}$ for durations of 60 s.

In procedure E1, at a power density of 6.94 W mm$^{-2}$, a yellow glow and smoke appeared over the surface of the shaft within 12 s, followed shortly by a flame along the laser fibre. At 35 s there was a yellow flame on the shaft; this did not spread away from the point of laser strike. The experiment was stopped after 45 s when a crust of silica ash had formed; this was removed to reveal that the shaft had been penetrated, with the metal rings broken.

In procedure E2, at a power density of 35.7 W mm$^{-2}$, a flame appeared at 10 s spreading along the laser fibre, followed by a glow and a flame localized to the point of laser strike. A crust of silica ash formed. After 60 s when the experiment was stopped, examination revealed that when the crust of ash was removed, the shaft underneath was penetrated and the metal rings broken. At 71.4 W mm$^{-2}$, there was an instant glow followed by a flame which spread over the surface of the shaft. Simultaneously, smoke appeared within the lumen of the shaft. The experiment was stopped at 15 s when there was a spreading fire which was extinguished by a fire extinguisher. When the laser fibre was pushed through the hole in the RLMA, there was a near-instant conflagration with laser strike: the flame burned within the shaft both towards the cuff and retrogradely towards the anaesthetic machine. The cuff exploded with a loud bang. The gas flow was turned off and the fire extinguisher was applied, but despite this, an incandescent glow remained over the surface of the shaft for 45 s.

In procedure E3, at a power density of 71.4 W mm$^{-2}$ with a mixture of oxygen and air flowing within the shaft, there was smoke within the shaft at 10–12 s, followed by a surface yellow flame and yellow glow inside the tube. At 45 s, the experiment was stopped: when the silica crust was removed, the tube was found to have been penetrated and the metal rings broken. Pushing the laser fibre through the hole in the shaft caused an instant glow and a flame at 10 s. It did not result in the conflagration seen when oxygen–nitrous oxide was used.

In procedure F (table 5), the air-filled cuff ruptured within 6 s at power densities as low as 0.37 W mm$^{-2}$ (accompanied by a characteristic "pop" and cuff deflation). Continued firing of the laser (at 1.22 W mm$^{-2}$ for up to 20 s) did not cause the ruptured cuff to ignite. With very low power densities (0.13 W mm$^{-2}$), the area of cuff struck by the laser darkened and slowly formed an "aneurysm": after 60 s of continuous firing, this area was found to be extremely brittle and disintegrated with the slightest manipulation. At the lowest power density (0.10 W mm$^{-2}$ for

| 0.37 | 10 | 20 | Saline | — | No effect | 2 | 2 |

60 s), this aneurysmal area formed but was not brittle and did not disintegrate.

In procedure G (table 6), a power density which had caused explosive cuff rupture within 6 s in the air-filled cuff (0.37 W mm$^{-2}$), had no effect after 60 s of continuous firing on the saline-filled cuff. At the highest power density used which had caused explosive rupture of the air-filled cuff within 3 s (1.22 W mm$^{-2}$), the saline-filled cuffs lasted between 5 and 11 s before (non-explosive) penetration caused saline to leak out in a small jet. There was less subsequent deflation compared with the air-filled cuff, as some saline remained in the cuff.

## Discussion

At laser power outputs and at distances of the laser fibre tip from the RLMA normally encountered in clinical practice, the RLMA was not penetrated or ignited by KTP laser strike. While some surface changes did occur, the layer of silica ash which formed appeared to protect the RLMA shaft from further damage (procedure B; table 1). However, the black line and lettering on the RLMA shaft were more vulnerable to the effects of the laser. Longer exposures to laser strike had a detrimental effect: a power density of 6.57 W.mm$^{-2}$ for 20 s had no effect (table 1), but a slightly higher power density of 6.94 W mm$^{-2}$ for 60 s caused shaft penetration (table 4). Similarly, a power density of 35.7 W mm$^{-2}$ for 20 s caused only surface changes (table 1), but after 60 s caused penetration (table 4). The air-filled cuff ruptured rapidly on laser contact at very low power densities; filling the cuff with saline had a protective effect.

Fried, Mallampati and Caminear[10] studied the effects of KTP laser strike on a selection of tracheal tubes. Using only one (extremely high) power density of 250 W mm$^{-2}$ for 60 s, they found the following tubes to ignite within 31 s: unwrapped PVC tubes (Sheridan and Mallinckrodt), unwrapped red rubber tubes (Rusch) and metallic-coated silicone tubes (Xomed Laser Shield). Only red rubber tubes wrapped with aluminium foil and corrugated stainless steel tubes (Mallinckrodt Laser-Flex) were resistant to the laser at this power density (although the silicone-covered corrugated steel tubes (Bivona Fome-Cuff) did suffer surface changes). The power density used in this study was different from that used in our study and direct comparison is therefore difficult, but the fact that red rubber tubes wrapped with aluminium foil and corrugated stainless steel tubes did not ignite suggests that these may be somewhat safer than the RLMA to laser strike. It is interesting that Fried, Mallampati and Caminear[10] also found the black marker line of the tracheal tubes to be less laser-resistant than the shaft.

Brimacombe and colleagues[12 13] tested the incendiary properties of the RLMA to carbon dioxide laser strike, and the results were similar to ours, although the relevant power densities differed with the different laser used. At 23.5 W mm$^{-2}$, the shaft was penetrated after 20–30 s but there was no ignition. Brimacombe and colleagues noted a layer of silica ash sitting on top of the crater, apparently "protecting" the shaft from further penetration or ignition (similar to our results in table 1). However, at very high powers (980 W mm$^{-2}$), the RLMA did ignite almost immediately. The cuff was also found to be less resistant, being penetrated within 5 s, but Brimacombe and co-workers did not test the effect of saline in the cuff or of laser on the black marker line.

Our study was an *in vitro* bench study. In the clinical situation, the risk of flammability may be affected by the presence of surrounding tissue or small particles of blood which may act to absorb laser energy and so cause ignition at lower power densities than the RLMA itself.

Our study provides no direct comparison of the RLMA with tracheal tubes to laser strike. There is controversy as to which tracheal tube is the most laser-resistant and which should ideally be compared with the RLMA.[6–10] Recognizing that RLMA are used by many anaesthetists in laser surgery of the upper airway, our main purpose was to document the laser-resistant properties of the RLMA alone, by using several experimental procedures in repeated studies. Further experiments of a different design are needed to compare the RLMA with tracheal tubes.

Our study was limited in that not every combination of conditions was tested. For example, the black marker line was tested at only one power density (table 2), and the effect of oxygen–nitrous oxide on laser strike on the cuff was not assessed. However, we feel that designing the experimental procedures to answer a sequence of questions enabled us to draw more practical conclusions from the study. For example, we can conclude with confidence that at a power density which does not affect the shaft (table 1), striking the black line increased the vulnerability of the RLMA (table 2); oxygen–nitrous oxide did not have such a marked effect (table 3).

We have attempted to emulate the laser strike which might *normally* occur in clinical practice. We have also been careful to express our results in terms of the incident laser power *density* which we believe is the relevant variable that determines outcome. Some previous studies have not adhered to this approach so rigorously.[6 13] Thus in most of the experiments, submaximal power outputs were used at distances of

2–5 mm from the shaft and 10–20 mm from the cuff. Most other studies also appear to have examined a different question, namely: "Does the RLMA or tracheal tube ignite at all?"[9,10] We do not think that this is a very useful question if the RLMA is then examined at power densities not found in clinical practice. We did, in fact, examine the effects under more extreme conditions and our conclusion does not differ in this respect from that which might be predicted: *virtually any device will ignite or be penetrated if the laser strike is powerful enough.*

Based on our findings, several recommendations may be made on the safe use of the RLMA in the presence of the divergent KTP laser.

(1) The surgeon should clearly exercise caution and avoid direct laser strike on the RLMA shaft or cuff. This risk is minimized if a Boyle–Davis gag without the Doughty modification is used and the gag is opened as widely as possible: in this situation neither the RLMA cuff nor the shaft can be seen.[14] The risk of airway obstruction using an unmodified gag might, however, be high,[15,16] and if this is the case then it would be sensible to use a modified gag and to protect the RLMA shaft by covering the slit with a dampened gauze or swab. The power output used should be the minimum required and laser duration should be limited. In this way, the risk of penetration of the shaft by the laser (which occurred in this study after 45–60 s at a power output of 6.94 $\mathrm{W\ mm^{-2}}$ and higher; table 4) is minimized.

(2) Consideration should be given by the manufacturers to produce RLMA in which there is no black marker line or lettering, or in which this is placed much higher up the shaft than it is at present. The purpose of the lettering is to identify the device as an RLMA (probably unnecessary), but more importantly, to identify its size. The purpose of the black line is to identify the midline of the shaft: when the device is inserted, this line should ideally be central and point cranially. It might at first be thought that this line serves a very important function. However, in a *reinforced* laryngeal mask, which has a flexible shaft, the portion of the shaft and so also the black line lying *outside the mouth* varies considerably and as such cannot accurately indicate the way in which the shaft or cuff is lying *inside the mouth*. The benefits of retaining the black line and lettering appear to be outweighed by the reduced ability of the RLMA to resist laser strike (table 2). Therefore, it is our contention that, for use with laser surgery to the head and neck, RLMA without the black line should be used.

(3) This study lends no direct support to the notion that the use of gases which support combustion (i.e. oxygen and nitrous oxide) markedly reduced the laser-resistant properties of the RLMA (table 3). It is clear that under some, extreme circumstances ignition can occur and it would therefore be prudent to consider using only air–oxygen mixtures rather than oxygen–nitrous oxide during maintenance of anaesthesia, unless there is a compelling reason to use nitrous oxide.

(4) The cuff is more vulnerable to laser strike than the shaft (table 5). Filling the cuff with saline affords protection and therefore is the safe method in the presence of lasers. Consideration might also be given to the use of methylene blue or a coloured inert indicator so that the operator knows if the cuff has ruptured. The disadvantages of using saline in the cuff are that the manufacturers only recommend filling the cuff with air and as not all of the saline can be withdrawn from the cuff after use, this may cause cuff rupture during autoclaving.[17] The cost–benefit balance of using saline thus remains to be determined.

(5) With the increasing use of lasers in clinical practice and especially with regard to tubes marketed specifically for use in laser surgery, it would be desirable that in future, manufacturers tested for and published tolerance levels of their devices to laser strike from a variety of lasers at different power densities.

## Acknowledgements

We thank Mr K Wood of Intavent Ltd, Reading, UK, for providing us with the reinforced laryngeal masks for study and Sister J. Slater and Staff Nurse D Nelson for operating the Laserscope surgical laser system.

COMMENTARIES

# Calculation of drug dosage and body surface area of children

J. A. LACK AND M. E. STUART-TAYLOR

## Summary

The *British National Formulary* and many reference textbooks recommend that drug dosages for children be calculated according to body surface area (BSA). Although many rules for drug dosage have been developed, based on age, weight and surface area, none has been accurate and simple enough for routine use. These rules are described, and one for clinical use: up to 30 kg, a child's drug dose may be (wt x 2)% of an adult dose; over 30 kg, (wt+30)% of an adult dose. If this percentage of an "adult" dose of a drug is used, not only is the BSA curve followed more closely than with the conventional mg $kg^{-1}$ regimen, but fewer major errors of prescription may be expected. (*Br. J. Anaesth.* 1997; **78**: 601–605).

**Key words**
Anaesthesia, audit. Children. Anaesthesia, administration schedule

The *British National Formulary* (*BNF*),[1] *Martindale's Pharmacopoea*[2] and many other reference textbooks state that the most reliable methods for calculation of children's drug doses are those based on body surface area (BSA). This principle has been commended for nearly 90 yr, but there is still no consistency in the guidance offered, and the same *BNF* uses a mixture of mg $kg^{-1}$, age and weight ranges in its recommendations.

All dosage rules based on a single physical dimension only hold good while that dimension is associated with other normal dimensions. Thus one could use an age-based rule if associated height and weight for that age were typical; however, there is substantial normal variation in height and weight with age (see below) and so weight is used more usually as the dimension for calculations. This however is still relatively unreliable, and therefore if better prediction of drug concentrations is required, a multidimensional rule is needed. Fortunately, this is usually beyond clinical needs.

The therapeutic ratio (the ratio of toxic to effective dose) for most drugs is more than 50%, so that some approximation may usually be made with safety. It would appear that for routine practice, an "accuracy" of 10–20% is reasonable; more than this complicates the mathematics substantially, and would not be justified because of individual differences in response. This generalization excludes those drugs which are given according to known individual requirements (e.g. insulin or digoxin), for which a prescribing rule is inappropriate.

A large number of children's drug dosage rules have been described,[3–5] almost all using percentages of an adult dose to calculate an appropriate child's dose—the notable exception being the commonly used "*n*" mg $kg^{-1}$ regimen. An advantage of these rules is that modifications to adult doses to allow for sickness in adults are appropriately incorporated into calculations for children. An obvious requirement of these percentage methods is that adult doses of the drug are known, but for the majority of anaesthetists this does not present a problem, and certainly no more difficulty than the different dosages at different ages noted in the *BNF*.

Reports in the literature quote many examples of prescription errors in children, of 2–10 times the recommended dose.[6–10] Many believe that the great majority of these errors would have been noticed if easily calculated percentages of a normal adult dose had been used, as the prescriber may readily check his mathematics by inspection of the values involved.

Dosage rules may be described as those based on age, weight or body surface area.

## Age-based rules

The earliest rules used age as the base. Augsberger[3] referred to Dilling's rule (age/20) as dating back to

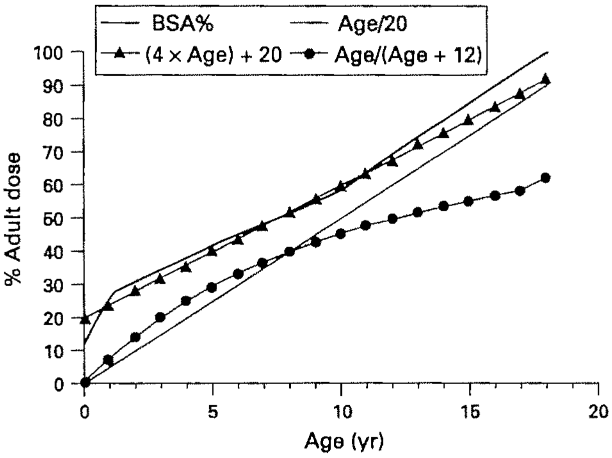

*Figure 1* Age-based rules at ages shown for calculation of childrens' drug dosages as a percentage of adult doses plotted using weights derived from standard growth tables

---

J. A. LACK, FRCA, DIC, Anaesthetic Department, Salisbury Hospital, Salisbury SP2 8BJ. M. E. STUART-TAYLOR, FRCA, Anaesthetic Department, Southampton General Hospital, Tremona Rd, Southampton SO16 6YD. Accepted for publication: January 10, 1997.

the 8th century. Those most commonly used:

age/20, (4×age)+20 and age/(age+12)

are shown in figure 1, plotted using weights for ages obtained from standard tables.[11 12] The normal variation of weight with age (from 3rd to 97th percentiles) is considerable, being least at 1 yr (+25% to −20% at 10 kg), and reaching a maximum at about 13 yr (+45% to −26% at 40 kg). The consequence is that these rules are highly unreliable.

If weight is unavailable, then (4×age)+20 provides the best fit to the BSA curve for normal sized children.

## Weight-based rules

Professor A. J. Clark of Edinburgh is said to have been the first to propose a weight proportional regimen for drug therapy.[13] His first rule was:

(wt (lb)/150) fraction of an adult dose.

This was improved in accuracy by Augsberger,[3] who substituted multiplication for division and added 10, suggesting:

((1.5×wt (kg))+10) percent of an adult dose.

However, this made it difficult to calculate, and this rule is not quoted widely. It is as good a linear fit as can be made to the BSA curve, reaching 100% at 60 kg (fig. 2).

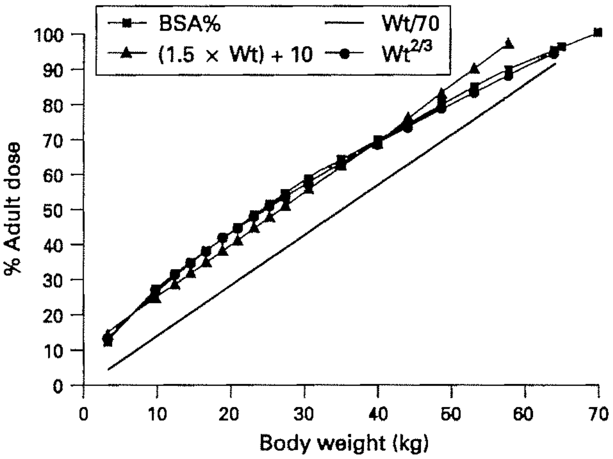

*Figure 2* Weight-based rules for calculation of childrens' drug dosages as a percentage of adult doses.

The most common regimen, mg kg$^{-1}$ dosages, has an attractive simplicity which has given it widespread popularity despite its disadvantages, namely: (a) it requires a complete set of drug dosages ($n$ mg kg$^{-1}$) to be learned for its purpose, and indeed different doses at different ages[1]; (b) the mathematics may not be as easy as a bedside rule demands, the decimal point sometimes being misplaced when tenths or hundredths of a mg kg$^{-1}$ are being multiplied; (c) it does not immediately relate to adult doses, so that inappropriate prescriptions are not immediately obvious; (d) assays of drug concentrations show that its use "under doses" for much of its range[14]; this varies from approximately −45% at 15 kg to −20% at 40 kg compared with the BSA graph (fig. 5).

## Body surface area calculation

Body surface area is recommended as the principal basis for drug dosage[15 16] as the rate of metabolism or redistribution of a drug is proportional to metabolic rate, which in turn reflects heat losses which, as for any warm object, are generally proportional to surface area. Many measurements of organ size, fluid compartment volumes and assays of blood concentrations of drugs correlate well with BSA.[13 17–20]

While this is valid for most ages, some decrease below the BSA proportional dose is in fact appropriate when prescribing for children of less than approximately 18 months, typically 10 kg, as below that age there are differences other than size that should be borne in mind, that is: in the neonate, many enzyme systems are immature; neonatal renal clearance is approximately 50% of adults, reaching adult values at approximately 6 months; the half-life for many drugs is therefore longer in neonates and infants; and children have a higher total body water percentage than adults (80% at birth, 70% at 3 months and 60% at 1 year, compared with approximately 55% for adults). This is important when considering the distribution volumes of drugs; in children less than 1 yr of age, distribution volume is relatively large for drugs that are water soluble, and small for those that are fat soluble.[14 21–23]

Moore, in 1909,[19] was the first to recognize the importance of BSA, saying that: "stating dosage in reference to body weight is not only inaccurate, but rests entirely on a wrong principle", and that it should be:

> "proportionately instead to the body surfaces or, in other words, proportionately to the two thirds powers of their weights, which leads to quite different doses." (1)

Moore was using the same formula as Meeh,[24] who is widely quoted. Clark gave his name to his second rule by reporting Moore's work in 1937,[13] again recommending dosage proportional to the two-thirds power of body weight.

The history of actual measurements of surface area is fascinating, with examples of marvellous ingenuity, from covering surfaces with paper, plaster or lead, to "wrapping a human in silk tights, charging up the silk as one would a Leyden jar, and calculating the surface by applying a metal plate of known area".[25] The power of 2/3 is the ratio of surface area to volume of cubes, spheres and other such solid objects, and in humans appears to be a quite reasonable approximation (fig. 2) for those of normal build, using a proportionality constant of approximately 12 for kilograms, that is 12×wt$^{2/3}$.[25] It is, however, unidimensional.

The first multidimensional formula for surface area to be used widely was proposed by DuBois and DuBois:[26]

$$S=W^{0.425}\times H^{0.725}\times 71.84 \qquad (2)$$

where S=surface area (cm$^2$), W=weight (kg) and H=height (cm).

The nomograms derived from this equation are those seen most often, as for example in *Martindale's Pharmacopoea*[2] or *Geigy Scientific Tables*[27] despite the fact that the investigators only measured nine subjects.

The definitive work on surface area is a monograph by Edith Boyd[28] who improved the formula as follows:

$$S=3.207W0.7285–0.0188 \log W\ H0.3 \quad (3)$$

where W=weight (g). She quoted the SD in her subjects as 7%.

Gehan and George[29] summarized all existing data, and suggested a further marginal improvement on the above equations, namely:

$$S=0.0235H^{0\ 42246}W^{0.51456} \quad (4)$$

In fact, equations (1–4) are within 5% of each other to a value of 15 kg in subjects with a normal build. Thin subjects would appear to have approximately 10% more surface area than predicted by equation (1), and fat subjects approximately 20% less,[25] but unfortunately the literature does not provide reliable data on variations of BSA with build.

## BSA-based rules

The nomograms constructed from these formulae provide the actual surface area, from which further mathematics provide the fraction of an adult dose, and thence the required dose, but this is hardly a bedside calculation.

The consensus has generally been that fixed tables of percentages of an adult dose derived from BSA[3 20 30] are a lesser evil than calculations requiring such higher mathematical powers, although they do require interpolation and the consequent possibility of introducing further errors. This approach, first suggested by Butler and Richie[17] and popularized further by Catzel and Olver as "The percentage method"[31] is also difficult to use in a clinical situation: the values may be learned by heart, but this is little more use than nomograms or a calculator. They appear to be the basis of the table given in the *BNF*[1] (which does not quote its source) and many current textbooks: Catzel's values (table 1, fig. 3) follow the BSA curve up to 40 kg, from which point they are 5% higher. Differences in the percentages recommended in different sources appear to arise from a combination of approximations and differences in the size of an "adult" (whether 140 lb, 65 kg or 70 kg). Much of this work was done in the early part of the century, since when the normal adult has increased in size.

*Table 1* Catzel's Recommended Doses of Drugs for Children[31]

| Age | Weight (kg) | % Adult dose |
|---|---|---|
| 2/52 | 3.2 | 12.5 |
| 2/12 | 4.5 | 15 |
| 4/12 | 6.5 | 20 |
| 8/12 | 8.5 | 25 |
| 12/12 | 10 | 28 |
| 18/12 | 11 | 30 |
| 3 yr | 15 | 33 |
| 5 | 18 | 40 |
| 7 | 23 | 50 |
| 10 | 32 | 60 |
| 12 | 40 | 75 |
| 14 | 45 | 80 |
| 20 | 65 | 100 |

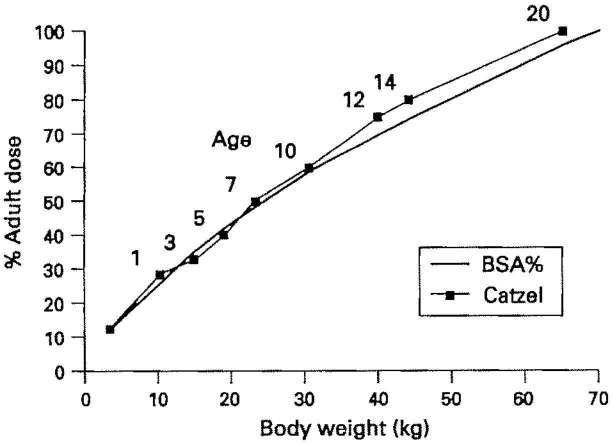

*Figure 3* Catzel's recommended doses of drugs for children as a percentage of adult doses.

## Salisbury rule

None of the rules described above is both simple and accurate enough for clinical use. A rule is needed that allows a dosage calculation that is approximately "correct", rather than having complicated mathematics in order to achieve academic accuracy, but getting the point wrong.

As a curve cannot be calculated easily with bedside mathematics, it was decided to use two straight lines crossing over at an appropriate point. As pointed out, the wt/70 (mg kg$^{-1}$) rule falls substantially below the BSA curve throughout its range, with consequent under dosing. Wt/50, which is the same as double the body weight as a percentage of the adult dose, makes for easier calculation and provides reasonable results up to 30 kg, although still deviating to the low side at low weights (thereby accommodating the reservations concerning infants described above). Over 30 kg, one may simply add 30 to the body weight to obtain the graph shown in figure 4, following the BSA curve closely.

The differences in the wt/70 (mg kg$^{-1}$) and Salisbury rules from the BSA curve are illustrated in figure 5.

Thus we propose the following rule in children:

less than 30 kg: weight×2
more than 30 kg: weight+30

percentage of the adult dose of a drug.

Expressed colloquially, this is: "to obtain the

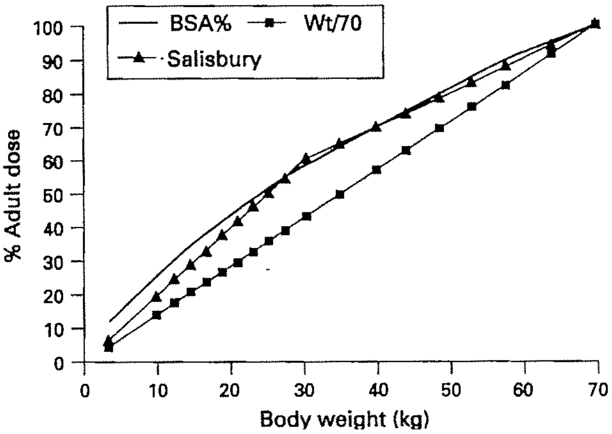

*Figure 4* The Salisbury rule for drug dosages for children compared with BSA and wt/70 (mg kg$^{-1}$).

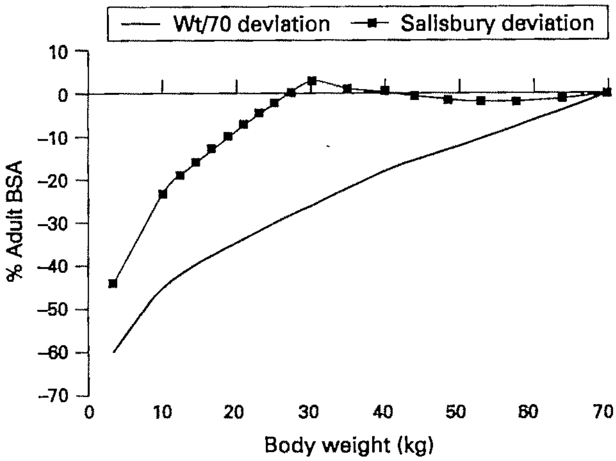

*Figure 5* Deviation from BSA of the wt/70 (mg $kg^{-1}$) and Salisbury rules.

*Table 2* Examples of drug dosage calculations using different rules. Most doses are rounded to the nearest milligram. n/r=Not recommended

| | Weight | | | |
|---|---|---|---|---|
| | 3.2 kg | 8.5 kg | 18 kg | 45 kg |
| Atracurium: "Adult" dose assumed to be 35 mg | | | | |
| 0.5 mg $kg^{-1}$ | n/r | 4 | 9 | 23 |
| Salisbury rule | n/r | 6 | 13 | 26 |
| Catzel/*BNF* | n/r | 9 | 14 | 28 |
| Thiopentone: "Adult" dose assumed to be 280 mg | | | | |
| 4 mg $kg^{-1}$ | 13 | 34 | 72 | 180 |
| Salisbury rule | 18 | 48 | 101 | 252 |
| Catzel/*BNF* | 35 | 70 | 112 | 224 |
| Morphine: "Adult" dose assumed to be 10 mg. "*BNF*" follows *BNF* guidance for different age/weight groupings | | | | |
| 0.1–0.2 mg $kg^{-1}$ | 0.3–0.6 | 0.9–1.7 | 1.8–3.6 | 4.5–9 |
| *BNF* mg $kg^{-1}$ | 0.5 | 1.7 | ~4 | 10 |
| Salisbury rule | 0.6 | 1.7 | 3.6 | 9 |
| Catzel | 1.25 | 2.5 | 5 | 8 |

BSA% from weight, under 30 double it, over 30, add 30".

Examples of this rule for some commonly used drugs are given in table 2. The results from the Salisbury rule fall into a safe area close to those recommended by the *BNF*. It is particularly useful that it removes the need to learn different doses at different ages. Therefore, for example, the dose for morphine is quoted in the *BNF* as: "<1 month, 150 μg $kg^{-1}$; 1–12 months 200 μg $kg^{-1}$; 1–5 yr 2.5–5 mg; 6–12 yr 5–10 mg". The Salisbury rule tracks these different doses accurately, so eliminating the need for different dosage recommendations at different ages.

We have been using this rule now for almost 10 yr. It has proved easy to use, and there has been no clinical evidence of inappropriate dosage.

## Summary

Nearly 90 yr ago the following suggestion was made: "For the great majority of drugs the method of stating dosage as so much per kilogram should be abandoned".[19]

It has often been repeated, and in order to provide a satisfactory alternative the Salisbury rule is that children should have:

"less than 30 kg, double the body weight; more than 30 kg, add 30 to the body weight"

percentage of the adult dose of a drug.

This rule gives as close adherence to fractional body surface area as is desirable, under dosing where immature development may be present, together with the added advantage of easier and more reliable calculation of the result.

# Multimodal approach to control postoperative pathophysiology and rehabilitation

H. KEHLET

## Summary

Major surgery is still associated with undesirable sequelae such as pain, cardiopulmonary, infective and thromboembolic complications, cerebral dysfunction, nausea and gastrointestinal paralysis, fatigue and prolonged convalescence. The key pathogenic factor in postoperative morbidity, excluding failures of surgical and anaesthetic technique, is the surgical stress response with subsequent increased demands on organ function. These changes in organ function are thought to be mediated by trauma-induced endocrine metabolic changes and activation of several biological cascade systems (cytokines, complement, arachidonic acid metabolites, nitric oxide, free oxygen radicals, etc). To understand postoperative morbidity it is therefore necessary to understand the pathophysiological role of the various components of the surgical stress response and to determine if modification of such responses may improve surgical outcome. While no single technique or drug regimen has been shown to eliminate postoperative morbidity and mortality, multimodal interventions may lead to a major reduction in the undesirable sequelae of surgical injury with improved recovery and reduction in postoperative morbidity and overall costs. (*Br. J. Anaesth.* 1997; **78**: 606–617).

**Key words**
Surgery, stress response. Pain, postoperative. Complications, morbidity.

Despite continuous advances in anaesthesia, surgery and perioperative care, major surgical procedures are still beset with undesirable sequelae such as pain, cardiopulmonary, infective and thromboembolic complications, cerebral dysfunction, nausea and gastrointestinal paralysis, fatigue and prolonged convalescence. Clearly, such morbidity may be related to the level of anaesthetic and surgical skill, but complications may occur regardless of skill and no single technique or drug regimen has been shown to eliminate postoperative morbidity and mortality.

A common feature shared by all surgical patients is the widespread changes in organ function, the so-called surgical stress response.[1] These functional changes are believed to be mediated by the trauma-induced endocrine metabolic changes and activation of several biological cascade systems (cytokines, complement, arachidonic acid metabolises, nitric oxide, free oxygen radicals, etc). Although these responses have evolved presumably to confer an advantage for survival, they may, if amplified and prolonged, also contribute to erosion of body cell mass and physiological reserve capacity.

The key question in our understanding of the pathogenesis of postoperative morbidity is therefore related to the pathophysiological role of the various components of the surgical stress response and whether or not a modification of such responses may improve surgical outcome. More simply, one may ask why a technically successful operation, whether a colonic resection, hip replacement or cardiac operation, should result in an unsuccessful outcome. Additionally, if such surgical sequelae are controlled, one may ask if patients could undergo major surgery on an ambulatory or semi-ambulatory basis.

This article reviews current techniques for controlling postoperative dysfunction by reducing surgical stress and pain. It is hypothesized that multimodal interventions may lead to a major reduction in the undesirable sequelae of surgical injury with accelerated recovery and reduction in postoperative morbidity and overall costs. This discussion will focus on elective surgery, excluding trauma and multiple organ failure, which have been reviewed elsewhere.[2]

## Perioperative risk factors and pathophysiological responses to surgery

Several perioperative risk factors and neurohumoral responses to surgical injury may contribute to postoperative morbidity (table 1).

### PREOPERATIVE FACTORS

### *Pre-existing disease*

*Table 1* Perioperative risk factors or pathophysiological responses to surgery that must be recognized, avoided or treated in order to control perioperative physiology and reduce morbidity

| Factors | Effects on outcome | Treatment |
|---|---|---|
| Pre-operative | | |
| Concomitant diseases | Increase overall morbidity | Preop. assessment and optimization of organ function |
| Malnutrition | Increase infective complications, delays recovery | Preop. nutrition |
| Alcohol abuse | Increase overall morbidity | Preop. abstinence or perioperative alcohol administration |
| Intra-operative | | |
| Surgical stress | Increase organ demands, leads to catabolism, immunosuppression and organ dysfunction | Minimally invasive surgery, neural block, pain relief, pharmacological interventions |
| Blood transfusion | Increase infectious complications and risk of cancer recurrence | Avoid unnecessary use of blood |
| Heat loss | Increase surgical stress responses during rewarming phase | Reduce heat loss or use external heating |
| Post-operative | | |
| Pain | Impairs organ function and delays mobilization and overall recovery | Effective, dynamic pain relief with multimodal pain therapy |
| Immunosuppression | Increase infective complications and cancer recurrence | Stress reduction, immunomodulation, avoid blood transfusion |
| Nausea/ileus | Delays recovery and early oral nutrition, enhances catabolism | Pain relief using neural block and NSAID, reduce use of opioid, pharmacological intervention (serotonin antagonists, etc) |
| Hypoxaemia | Increase risk of cardiac, cerebral and wound complications (infection/healing) | Oxygen administration, mobilization, stress reduction, avoid sleep disturbances |
| Sleep disturbances | May increase postoperative hypoxaemia, fatigue and enhance stress | Stress reduction, pain relief, reduce use of opioid, reduce noise and night time interventions |
| Catabolism/muscle loss | Increase all-over morbidity and fatigue, delays recovery | Stress reduction, pain relief, active rehabilitation, early oral nutrition, electrical muscle stimulation, growth factors |
| Immobilization | Increase risk of thromboembolic and pulmonary complications, increase fatigue, hypoxaemia and loss of muscle | Pain relief, active rehabilitation |
| Drains/nasogastric tubes/traditions | Delays recovery, may increase infectious complications | Avoid unnecessary use, revise perioperative care programme |

organ dysfunction are strong determining factors of postoperative complication rates and duration of hospital stay.[3] Accordingly, several clinical guidelines and indices have been developed to assess cardiovascular,[4] pulmonary[5 6] and thromboembolic[7] risks. Such information may serve as a basis for quantifying perioperative risk and outline indications for prophylactic therapy. However, such predictive scoring systems do not *per se* reduce postoperative morbidity, and may be successful only when preoperative optimization of organ function reclassifies a high-risk patient into a more low-risk group.

### *Malnutrition*

Malnutrition is a well established perioperative risk factor, and several nutritional assessment scores have been defined.[8] However, pre- and postoperative nutritional support with parenteral nutrition has been shown to reduce morbidity only in high-risk, malnourished patients.[8]

### *Alcohol abuse*

Recently, preoperative alcohol abuse, even without overt alcohol-related organ dysfunction, has been described as an important operative risk factor.[9] The mechanisms include alcohol-induced immunosuppression, subclinical cardiac dysfunction and an amplified hormonal response to surgery.[9]

## INTRAOPERATIVE FACTORS

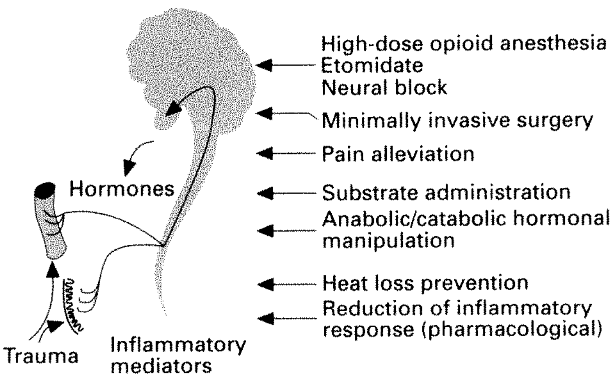
### *Surgical stress*

During and after surgical injury, the body responds with profound changes in neural, endocrine and metabolic systems in addition to alterations in organ functions.[1] These changes are characterized by increased secretion of catabolic hormones, decreased secretion or effects of anabolic hormones, hypermetabolism and increased cardiac work caused by autonomic system activation, impaired pulmonary function, pain, gastrointestinal side effects with nausea and ileus, a change in the coagulatory–fibrinolytic systems favouring coagulation and thrombosis, and loss of muscle tissue and immunosuppression.

Although the surgical stress response may represent a universally conserved cellular defence mechanism,[10] the stress-induced changes in postoperative organ function may also be implicated in the development of postoperative complications. Accordingly, the concept of "stress free anaesthesia and surgery" to attenuate the trauma-induced physiological responses with subsequent reduction of morbidity has been proposed.[11] In elective clean surgery the main release mechanism of the stress response is afferent neural stimuli from the surgical area.[12] In addition, several humoral substances such as cytokines, arachidonic acid cascade metabolites, nitric oxide, endotoxins and other biological cascade systems are involved.[1] The surgical stress response is related to the magnitude of surgical injury, and correspondingly lower morbidity rates are observed after minor surgical procedures, including minimally invasive surgery.

Based on the concept of "stress free anaesthesia and surgery" several strategies to reduce or prevent the surgical stress response have been developed[12 13] (fig. 1). A reduction in the degree of surgical trauma by minimally invasive surgery reduces protein catabolism and markers of inflammation (IL-6 and CRP), pulmonary dysfunction and convalescence, while early responses of catecholamines, cortisol and blood glucose are less modified.[14] The type of general anaesthesia for operation has no important effect on the stress response,[12 15 16] except for high-dose opioid anaesthesia which may inhibit intra-, but not postoperative catabolic hormonal responses.[15] Blocking the afferent neural stimulus by various neural block techniques with local anaesthetics is very effective in reducing the classical catabolic response to operation,[12 16 17] especially in lower body procedures and with the use of continuous extradural analgesia. Thus the usual increase in cortisol, catecholamines and glucose concentrations can be prevented, insulin resistance reduced, and glucose tolerance and nitrogen economy improved.[12 16 17] The unfavourable changes in the coagulatory–fibrinolytic systems are also modified in favour of less thrombosis formation, while most changes in immune function and markers of inflammation (acute phase proteins, IL-6) are unaltered by neural block and concomitant hormonal inhibition.[12 16 17] Pain relief by other techniques such as extradural or systemic opioids, NSAID or clonidine are less effective than neural block with local anaesthetics.[12 16]

Other strategies include administration of non-specific substrates[13] or specific fuels such as glutamine, arginine, omega-3 fatty acids, and growth factors and anabolic hormones, all of which may reduce catabolism.[13] Pharmacological reduction in the inflammatory response may include various cytokine (TNF, IL-1) antagonists, free oxygen radical scavengers and other agents inhibiting neutrophil activation and migration, but these measures have not yet been tested in elective surgery. So far, only glucocorticoids which counteract several proinflammatory substances (cytokines, complement, arachidonic acid cascade metabolites) have been studied in elective surgical procedures. These results suggest that a single large preoperative dose of methylprednisolone reduced pain, hyperthermia, IL-6 and PGE$_2$ responses, and improved conventional impairment in pulmonary function.[18] Obviously, any modulation in inflammatory response has to be weighed against potential side effects, including impaired wound healing and increased risk of infection. So far these questions have not been examined in large-scale studies.



High-dose opioid anesthesia
Etomidate
Neural block
Minimally invasive surgery
Pain alleviation
Hormones
Substrate administration
Anabolic/catabolic hormonal manipulation
Heat loss prevention
Reduction of inflammatory response (pharmacological)
Trauma
Inflammatory mediators

*Figure 1* Interventions which may reduce the stress response to surgery.

In summary, although a reduction in surgical stress may be attractive based on neural block studies, further studies are needed to define those responses which should be suppressed and those which should be enhanced in order to improve outcome. Consequently, the most rational and effective anti-stress or anti-catabolic therapy has not been designed.

### *Heat loss*

Unintended intraoperative heat loss may be a significant risk factor leading to increased stress responses (cortisol, catecholamines, nitrogen loss) and cardiovascular complications.[19–21] Conservation of body heat and prevention of intraoperative hypothermia should therefore be provided whenever pronounced heat loss is expected, in order to reduce the stress responses to rewarming with increased oxygen consumption, catabolic hormone secretion and nitrogen loss.[19 22] This approach is supported by the finding that prevention of intraoperative hypothermia reduced wound infection rate and hospital stay in patients undergoing colonic surgery.[23]

### *Blood transfusion*

Increased blood loss and use of perioperative blood transfusion correlate with increased risk of infective complications and probably recurrence after cancer surgery.[24] The risk is related mainly to the content of white cells and non-cellular transfusion components.[24] Even the use of autologous blood transfusion with prolonged storage time may have detrimental effects, as toxic mediators (histamine, PAI-1, myeloperoxidase, etc) are released from leucocytes and platelets during storage for more than 2 weeks of any blood product containing these components.[24] Leucocyte-depleted blood by bedside filtration may significantly reduce postoperative infective complications.[25]

## POSTOPERATIVE FACTORS

### *Pain*

All surgical procedures are followed by pain, which may amplify endocrine metabolic responses, autonomic reflexes, nausea, ileus and muscle spasm, and thereby delay restoration of function. Optimal treatment of postoperative pain is mandatory in order to enhance recovery and reduce morbidity.

Presently, several techniques are available to treat postoperative pain effectively.[26] Initial therapy in minor to moderate sized procedures should involve a multimodal approach using incisional local anaesthetics, systemic NSAID and opioids.[26 27] With more severe pain, central neural block techniques using continuous extradural analgesia with local anaesthetics combined with small doses of opioids are necessary to provide dynamic pain relief, that is pain relief that allows normal function.[26 27] Patient-controlled analgesia techniques with opioids provide a high degree of patient satisfaction,[28] but pain relief during mobilization is less than that with the extradural combination techniques.[29]

The effect of improved pain relief *per se* on postoperative outcome is debatable.[12 16 17 26 28] Most controlled studies of extradural analgesia and patient-controlled analgesia have not demonstrated clinically important effects on outcome, except on some specific variables such as thromboembolism, gastrointestinal ileus and intraoperative blood loss (see below).[12 16 17 26 28] Surprisingly, effective pain relief does not automatically lead to increased ambulation and reduction in hospital stay.[30] Nevertheless, effective postoperative pain relief is a prerequisite to attain improved postoperative outcome, and when integrated into an active rehabilitation programme (see below) may reduce the surgical stress response, organ dysfunctions and improve gastrointestinal motility, to allow early oral nutrition and to facilitate early mobilization.

### *Immunosuppression*

Much evidence has emerged to demonstrate pronounced trauma-induced alterations in immunological systems. Major surgery causes immunosuppression with reduced delayed hypersensitivity response to recall antigen stimulation, T-cell-dependent antibody response, IL-2 production and HLA-DR antigen expression, IFN-$\gamma$ production and T-cell blastogenesis.[31] In contrast, neutrophil and macrophage functions are activated with increased release of oxygen radicals and TNF, and chemotaxis.[31] Smaller operations, including minimally invasive surgery, may result in less change in immune function.[14 31] Perioperative blood transfusion enhances postoperative immunosuppression.[24]

The clinical consequences of pre- and postoperative immunological changes are increased susceptibility to infective complications,[31–33] and probably increased risk of recurrence after cancer surgery.[31] Therefore, much effort has been expended to modify post-traumatic immune function, including the use of thymopentine, immunoglobulins, granulocyte colony-stimulating factor, glutamine, arginine and omega-3 fatty acids, PGG-glucan, histamine-2 receptor antagonists and other biological response modifiers.[31 33] Although most of these studies have shown partial improvement in post-traumatic immunosuppression and a tendency towards improvement in outcome, no final conclusions or clinical recommendations can be made. An exemption is the well documented relationship between the use of blood transfusion, immunosuppression and risk of infective complications.[24 25] Reduction in extent of trauma by minimally invasive surgery is presently the most effective technique to reduce immunosuppression and risk of infection.[14]

### *Nausea and ileus*

Nausea, vomiting and ileus are among the most common postoperative complaints and in addition to being unpleasant they may also be important determining factors in postoperative rehabilitation. Thus early enteral nutrition is critical in reducing post-traumatic infective complications[34] and may also reduce catabolism.[13] The pathogenesis of postoperative nausea, vomiting and ileus is multifactorial, being related to type of surgery, gender, choice of anaesthesia and use of opioids.[35 36] Efforts to reduce nausea and vomiting include the use of antiemetics, with serotonin antagonists being most effective, in addition to effective pain control and opioid sparing with the use of local anaesthetics, and NSAID.[35–37] Continuous extradural analgesia with local anaesthetics, but not opioids, is effective in reducing postoperative ileus[12 16 17 29] because the associated sympathetic intestinal nerve block increases motility. Such techniques should therefore be used whenever possible, in order to facilitate early oral nutrition and postoperative recovery.

### *Postoperative hypoxaemia*

Constant postoperative hypoxaemia lasts for 2–5 days after major abdominal surgery with superimposed episodic hypoxaemia occurring especially at night.[38] The mechanism of constant hypoxaemia is primarily a pulmonary shunt caused by reduction in functional residual capacity,[39] while postoperative episodic hypoxaemia may be caused by ventilatory arrhythmias (hypoventilation and apnoeas) related to rebound rapid eye movement (REM) sleep on the second and third nights after operation.[38 40]

Late postoperative hypoxaemia may be involved in cardiac, cerebral and wound complications. Thus postoperative myocardial ischaemia is a strong predictor of postoperative cardiac complications after non-cardiac operations[41 42] and some studies have shown a temporal relationship between the occurrence of episodic hypoxaemia and myocardial ischaemia and/or arrhythmias in the late postoperative period.[38] As episodic hypoxaemia is most pronounced at night and unexpected postoperative death seems to occur more often at night than during the day or evening,[43] further studies are urgently needed on the pathogenesis of hypoxaemia and its effect on cardiac morbidity. Late postoperative hypoxaemia may also be a factor in wound complications as reduced supply of oxygen to the surgical wound impairs healing[44] and lowers resistance against bacterial wound infection.[45] Finally, postoperative impairment in cognitive function and delirium may be related to postoperative hypoxaemia[46] and postoperative delirium has been treated successfully with supplementary oxygen.[47 48]

As late postoperative hypoxaemia may have important clinical implications for cardiac, cerebral and wound complications, the choice of analgesic technique may be important, as neural block techniques with local anaesthetics and avoidance or reduced use of opioids may improve oxygenation.[38] Also, early ambulation and avoidance of the supine position may improve postoperative oxygenation.[49] Although oxygen therapy may reduce postoperative tachycardia[50] and be of potential advantage for the wound[44 45] and brain,[46] no definite indications for dosage and duration of postoperative oxygen therapy have been determined. Nevertheless, based on the above mentioned considerations and duration of postoperative hypoxaemia, routine postoperative oxygen administration may be indicated for the first 2–4 days in high-risk surgical patients and in patients with an $Sp_{O_2}$ less than 93%. The use of late postoperative pulse oximetry monitoring is therefore recommended. In the early postoperative period in the post-anaesthetic care unit, pulse oximetry monitoring may indicate changes in care, although a reduction in all-over morbidity has not been documented.[51]

### *Postoperative sleep disturbances*

Sleep patterns are severely disturbed in postoperative patients, with a decrease in total sleep time, elimination of (REM) sleep and a marked reduction in slow wave sleep (SWS).[40 52] The pathogenesis of postoperative sleep disturbances is multifactorial, and includes afferent neural stimuli (surgical stress), cytokines, pain, use of opioids, and noise and awakenings during monitoring and nursing procedures.[52] Postoperative sleep disturbances with REM sleep rebound on the second to fourth night may be related to sleep-induced apnoeas, nocturnal hypoxaemia and profound sympathetic activation with haemodynamic instability.[40 52] Therefore, postoperative sleep disturbances may be a pathogenic factor in postoperative cardiac dysfunction and complications, in addition to mental dysfunction.[52] Prevention and treatment of postoperative sleep disturbances have not been evaluated, but may involve reduction in surgical stress, noise, inconvenient nursing procedures and provision of effective pain relief with reduced use of opioids.[52] Laparoscopic surgery may reduce postoperative sleep disturbance compared with open laparotomy.[53]

### *Immobilization*

Traditional perioperative care involves bed rest, although it is well known that immobilization may increase the risk of thromboembolic and pulmonary complications.[54] Furthermore, bed rest predisposes to orthostatic intolerance and instability during standing, and to an increased loss of muscle tissue and function.[54] Postoperative hypoxaemia is also more pronounced in the supine position[49] with its potential detrimental effects on cardiac, cerebral and wound function (see above). Finally, early ambulation may improve wound healing.[55 56] Despite this evidence, early ambulation has been controversial in the history of surgery,[57] although the movement towards ambulatory or semi-ambulatory surgery has supported the concept of early ambulation and rehabilitation in order to improve outcome and reduce costs. The prerequisite for early ambulation and active rehabilitation is effective dynamic pain relief using the multimodal approach (see above).

### *Catabolism and muscle wasting*

Postoperative catabolism and muscle wasting are important factors for development of postoperative fatigue[58] and in overall recovery. Catabolism is mediated by the surgical stress response, postoperative immobilization and semi-starvation. These physiological changes after routine major surgery may persist for up to several months in patients receiving established routine care.[59] Recovery of muscle strength is delayed further in old compared with young patients,[60] suggesting special efforts to be made in this high-risk group. Therapeutic interventions in order to reduce catabolism and loss of muscle tissue and function may include stress reduction (see above), enforced early mobilization, electrical muscle stimulation[61] and early oral nutrition,[8] supported by pain treatment techniques to accelerate restoration of gastrointestinal motility (see above). Furthermore, a variety of nutritional substrates, growth hormone or other growth factors may reduce catabolism and maintain muscle mass.[13 62]

### *Drains/nasogastric tubes/traditions*

Perioperative guidelines are usually developed according to traditional practice, which most often are not validated by scientific studies. These often include the use of drains and nasogastric tubes in addition to traditional "observation" periods in hospital. The traditional routine use of drains seems unnecessary based on available evidence from controlled clinical studies in several operations, including cholecystectomy,[63] joint replacement,[64] colonic surgery[65] and radical hysterectomy.[66] Enhancement of recovery and reduction of hospitalization may also be achieved by home discharge with a drain in place after mastectomy.[67 68] The routine use of nasogastric tubes after elective abdominal surgery is unnecessary and may even contribute to pulmonary complications.[69 70] Furthermore, routine use of nasogastric decompression may delay oral intake and thereby slow recovery because of other sequelae and semi-starvation (see above). Finally, traditional restrictions on early oral intake after abdominal surgery should be abandoned, as they are not supported by scientific data.[71]

These findings therefore suggest that increased efficiency and reduced costs can be achieved if traditional care programmes are adjusted to the available scientific data.

## Postoperative morbidity

Surgical procedures may be followed by undesirable sequelae such as cardiac, pulmonary, thromboembolic and infective complications, etc, which may not be related directly to imperfections in surgical or anaesthetic technique but rather to various perioperative risk factors and pathophysiological

*Table 2* Common postoperative complications, their pathogenesis and prevention

| Complication | Pathogenic factors | Interventions |
|---|---|---|
| Cardiac | Cardiac stimulation (surgical stress), hypoxaemia, fluid disturbances | Stress reduction (minimally invasive surgery, neural block, pain relief), oxygen administration, avoid heat loss and fluid overloading |
| Pulmonary | Impaired pulmonary and diaphragmatic function (surgical stress), pain, immobilization, fluid disturbances | Stress reduction (minimally invasive surgery, neural block, pain relief, physiotherapy, glucocorticoids), avoid supine position and fluid overloading |
| Thromboembolism | Altered coagulatory/fibrinolytic balance (surgical stress), immobilization | Antithrombotic prophylaxis, stress reduction (neural block, pain relief), mobilization |
| Cerebral dysfunction | Surgical stress, hypoxaemia, psychoaffective drugs, withdrawal syndromes | Stress reduction (minimally invasive surgery, neural block), oxygen administration, mobilization, avoid unnecessary opioid, psychoaffective drugs and development of drug withdrawal |
| Infection | Contamination, immunosuppression (surgical stress), hypoxaemia | Avoid contamination, use antibiotic prophylaxis, stress reduction (minimally invasive surgery, neural block), immunosupportive therapy, nutrition, oxygen administration, mobilization, remove catheters and drains as soon as possible, avoid unnecessary blood transfusion |
| Nausea and gastrointestinal dysfunction | Afferent stimulation (surgical stress), anaesthetics and opioid analgesics | Stress reduction (minimally invasive surgery, neural block, pain relief), avoid unnecessary opioids, use antiemetics |
| Impaired wound healing | Malnutrition, catabolism, (surgical stress), hypoxaemia, infection | Stress reduction (minimally invasive surgery), oxygen administration, mobilization, avoid infection, provide pre- and postoperative nutrition |
| Fatigue, reduced functional capacity and convalescence | Loss of muscle tissue and function, (surgical stress), immobilization and impaired cardiovascular adaptation to exercise, malnutrition | Stress reduction (minimally invasive surgery, neural block, pain relief), early oral nutrition and ambulation |

responses, including the effects of the surgical stress responses discussed above (table 2).

### CARDIAC COMPLICATIONS

Cardiac complications occur in 1–3% of patients undergoing major surgical procedures, with a higher incidence (2–15%) in those patients with preoperative cardiac risk factors.[42] Although improved intraoperative monitoring and cardiovascular support therapy have reduced cardiac morbidity during operation, most cardiac morbidity occurs from 1–4 days after operation, calling for more attention towards pathophysiological mechanisms of cardiac dysfunction during this period. The pathogenesis of postoperative cardiac morbidity is probably multifactorial, but increased sympathetic stimulation with tachycardia, cardiac hypermetabolism and increased work,[42] together with postoperative reduction in oxygen supply (hypoxaemia) may be most important. Reduction of post-surgical hypermetabolism and sympathetic drive may be achieved by pain treatment, where extradural local anaesthetic techniques are most effective and promising.[12,16,17] However, the evidence for a reduction in postoperative cardiac morbidity by extradural analgesic techniques remains inconclusive, possibly because optimal techniques have not been used and extended sufficiently into the postoperative period, and other risk factors, such as hypoxaemia or fluid overloading, have been neglected. Early postoperative systemic opioid analgesic treatment may reduce cardiac ischaemia,[72] but the overall clinical advantage has not been documented.

Future reduction in cardiac morbidity will probably involve stress reduction by effective pain alleviation techniques, together with therapeutic intervention against episodic and constant hypoxaemia, with a focus on the late postoperative period.

### PULMONARY COMPLICATIONS

Postoperative pulmonary complications (atelectasis, pneumonia) are assumed to be related to the obligatory postoperative impairment in pulmonary function.[39] In addition, intraoperative factors, including general anaesthesia and supine position, lead to impaired pulmonary function and atelectasis,[73,74] which may have further detrimental effects in the postoperative period. The pathogenesis of postoperative impairment of pulmonary function includes a pain-induced decrease in pulmonary mechanics and neurally reflex-mediated inhibition of diaphragmatic function.[5,39] In addition, various humoral cascade systems, arachidonic acid metabolites, cytokines, endothelial adhesion factors, etc, may contribute.[75] Finally, routine postoperative care involving the supine position for several hours daily may impair pulmonary mechanics and oxygenation.

So far, no technique is available to prevent postoperative impairment of pulmonary function and pulmonary complications. During operation a decrease in inspired oxygen concentration[76] and re-expansion of the lungs[77] may reduce or prevent the risk of atelectasis. The effect of chest physiotherapy (conventional or incentive spirometry) is debatable,[78,79] although a slight decrease in complication rate may be obtained.[79] However, these techniques have not been documented to be effective after postoperative pulmonary complications have developed.[79] Deep breathing exercises may be sufficient in low-risk patients and incentive spirometry reserved for high-risk patients.[80] Effective pain relief may improve, but not eliminate, postoperative pulmonary morbidity.[12,16,17] Changing position from the supine to the sitting or standing position is of obvious advantage[49,74] but requires effective pain relief to allow for sufficient ambulation. Also, pharmacological modification of some of the humoral cascade responses with preoperative glucocorticoid administration may have favourable effects on both pain and pulmonary functional impairment.[18] Finally, reduction in trauma by minimally invasive surgery improves postoperative pulmonary function and reduces pulmonary complications.[14]

Despite currently available therapeutic measures (intraoperative management, postoperative pain relief, pharmacological treatment, minimally invasive surgery, position changes and ambulation) postoperative pulmonary complications continue to be clinically important. However, intervention studies have mostly investigated unimodal therapy, but multimodal intervention may be more promising (see below).

## THROMBOEMBOLIC COMPLICATIONS

Postoperative thromboembolic complications continue to be an important determinant of outcome, despite the existence of several prophylactic regimens.[7] The pathogenesis of postoperative thromboembolism is the unfavourable change in all three components of Virchow's triad with a decrease in lower extremity blood flow, hypercoagulability and increased thrombocyte aggregation, impaired fibrinolysis and loss of vessel wall integrity. Amplifying factors are concomitant diseases and immobilization. Extradural analgesia with local anaesthetics may have favourable effects on all components of Virchow's triad.[12 16 17]

Several controlled studies have documented a pronounced reduction in thromboembolic complications (lower extremity thrombosis, vascular graft thrombosis and pulmonary embolism) after hip procedures, open prostatectomy, knee replacement and vascular surgery with the use of extradural anaesthesia and analgesia.[12 16 17] The effect of minimally invasive surgery on postoperative thromboembolic complications remains to be clarified. Although the reduction in trauma produced by laparoscopic procedures may reduce undesirable pathophysiological changes in coagulation and fibrinolysis, positioning in the reverse Trendelenburg position and pneumoperitoneum may have the opposite effects.[81] However, as early ambulation may be feasible after most minimal invasive procedures, these negative intraoperative factors may not be clinically important.

In summary, much evidence has accumulated that various single modality measures (antithrombotic regimens with heparins, systemic anticoagulation therapy, dextran, mechanical devices, extradural analgesia, ambulation) have resulted in a reduction in postoperative thromboembolism. Further reductions may be possible, and a multimodal approach, combining these techniques in accelerated programmes (see below) should be studied.

## CEREBRAL DYSFUNCTION

Delirium or other acute confusional states are common postoperative complications associated with higher mortality and complication rates, poor functional recovery and longer duration of hospital stay.[82 83] The incidence in major elective, non-cardiac operations in patients >50 yr may be approximately 5–10%.[82] Specific risk factors are age >70 yr, self-reported alcohol abuse, poor preoperative cognitive and functional status, and markedly abnormal preoperative serum electrolyte concentrations.[82] In addition, the use of psychoactive medications such as opioids (meperidine) and benzodiazepines may contribute to postoperative delirium.[84] Finally, postoperative hypoxaemia[38] and sleep disturbances[52] have been suggested to be risk factors for postoperative delirium. As several of these factors are involved in the surgical stress response, postoperative delirium may be improved by stress reduction using efficient neural block techniques. However, the data available from several controlled studies of such techniques have not demonstrated a reduction in postoperative delirium.[12 16 17 85] Unfortunately, in most of these studies single or short-term treatment was given, without taking advantage of the possibilities of early ambulation and restoration of pulmonary and muscle function. Provision of opioid-sparing analgesia with NSAID or local anaesthetics may be expected to reduce postoperative delirium, but more data are needed for a definitive conclusion.[37 86] Postoperative oxygen therapy has been effective against delirium in only a few small-sized studies.[47 48]

In summary, most studies have involved unimodal intervention strategies, and no major improvement in cerebral postoperative outcome has been documented from such studies. In contrast, multimodal intervention with oxygen therapy, early surgery and maintenance of cardiovascular stability in high-risk patients undergoing acute hip surgery showed a substantial reduction in postoperative acute confusional states and hospital stay.[87] In future, further improvement in cerebral outcome should be sought by multimodal intervention in accelerated stay programmes, including effective pain relief with enforced mobilization and nutrition (see below).

## INFECTIVE COMPLICATIONS

Despite rational and data-based guidelines for antibiotic prophylaxis, infective complications at the surgical site (the wound) or remote places (abscesses, sepsis, multiple organ failure) remain major postoperative morbidity problems. As host defence mechanisms are important to combat infection, efforts should be directed towards counteracting undesirable changes in pre- and postoperative immune function (see above). Such measures include reduction in blood loss and transfusion, enteral nutrition, immunomodulating drugs, use of minimally invasive surgical techniques and measures to avoid late postoperative hypoxaemia.

## GASTROINTESTINAL DYSFUNCTION

Postoperative gastrointestinal dysfunction includes motility disturbances resulting in nausea, vomiting and ileus, and other functional deficiencies which reduce the barrier against translocation of endotoxin and bacteria from the intestinal lumen.

Development of nausea, vomiting and ileus is dependent mainly on the site of injury, anaesthetic technique and use of opioids (see above). The mechanism of reduced postoperative stomach and colonic motility is predominantly neurogenic with activation of inhibitory sympathetic efferents.[12 16 17] The ileus reducing effect of continuous extradural local anaesthetic techniques is well documented.[12 16 17 29] Nausea and vomiting may also be a result of direct neurogenic stimulation of the vomiting centre, which may be counteracted by serotonin antagonists and reduced use of opioids.[35 36 88]

A systemic or gut insult may promote breakdown of gastrointestinal mucosal barrier function, leading to translocation.[89 90] Although experimental studies suggest that impaired mucosal barrier function and translocation may further increase the systemic stress response caused by absorption of endotoxin and other bacterial products, the prevalence of gut translocation and its relationship to infective and other complications remain to be established in surgical patients.[89 90] The role of fasting and route of feeding may influence the stress response to surgical injury or other injuries, as oral nutrition was found to reduce the response compared with parenteral nutrition in some[91] but not all[92] studies. Nevertheless, even short- term fasting for 1–2 days enhances catabolism.[93]

As controlled clinical studies have shown that early enteral nutrition is effective in reducing nitrogen loss,[13 94] postoperative infective complications and duration of hospital stay,[34 94] in addition to improving immune function,[95 96] every effort should be made for early institution of enteral nutrition. The relative importance of different components in the enteral nutrition regimens (standard diet *vs* enrichment with glutamine, arginine and omega-3 fatty acids) remains to be established.[13 95 96] Provision of early enteral nutrition requires a combined effort with omission of unnecessary nasogastric tubes, use of antiemetics and effective pain regimens to enhance gastrointestinal motility, again representing a multimodal effort in order to reduce postoperative organ dysfunction.

### IMPAIRED WOUND HEALING

In the postoperative patient several factors may contribute to impaired healing and susceptibility to infections. Such mechanisms include hypoxaemia[44 45] and the response to injury and sepsis.[97] Although the relationship between nutrition and wound healing remains to be clarified,[98] early enteral nutrition may enhance wound healing.[99] Furthermore, oxygen administration may reduce infection[45] and be expected to improve wound healing.[44] Therefore, efforts to improve oxygenation such as ambulation[49] or oxygen therapy are important. Early ambulation may also improve wound healing by other unknown mechanisms.[55 56] However, in some operations, for example mastectomy, prolonged immobilization may reduce formation of seromas.[100] Finally, the use of growth factors may have a future role in the postoperative management of wound dysfunction.[13]

In summary, effective therapeutic measures against impaired wound healing and infection may include a multimodal approach towards infective complications (see above), and aggressive pain treatment allowing early ambulation, prevention and treatment of hypoxaemia and early oral nutrition. However, although these views appear rational, there are no controlled data to support this concept.

### FATIGUE AND CONVALESCENCE

Postoperative fatigue is a common feature of the recovery phase and is related to the magnitude of surgical injury, postoperative impairment of nutritional status, loss of muscle mass and function, and postoperative impairment in cardiovascular adaptation to exercise.[58 101] Also, the preoperative level of fatigue may increase the risk of postoperative fatigue, while the level of preoperative anxiety is less important.[58 101] Reduction in trauma and stress by minimally invasive surgery reduces postoperative fatigue and preserves functional capacity.[102] Single modality treatment with effective pain control[58] or nutrition[58 99] have not significantly reduced postoperative fatigue. Most importantly, if nurses and physicians confine patients to bed in the postoperative period, the positive effects of effective pain treatment may not be obtained.[30] Therefore, a multimodal approach to avoid postoperative catabolism and loss of muscle tissue and function seems rational. Although no controlled data are available, such a combined approach seems to be effective in reducing postoperative fatigue and convalescence after colonic surgery.[103 104]

## Multimodal approach to control postoperative pathophysiology and rehabilitation—a unifying concept

The risks and morbidity associated with surgical procedures have been steadily decreasing in recent decades, primarily because of improvements in patient preparation for surgery, and anaesthetic and surgical techniques during operation. One of the most impressive changes has been the introduction of minimally invasive surgery. These developments have also contributed to increased use of ambulatory and semi-ambulatory settings for surgical procedures. Counteracting these beneficial developments is the fact that the proportion of elderly patients presenting for surgery is increasing, and that they represent a high-risk group with increased postoperative morbidity and mortality. Thus despite improvements, major surgical procedures may continue to be beset with well known "medical" complications, including myocardial infarction, delirium, pulmonary dysfunction, thromboembolism, infective complications, fatigue and prolonged convalescence.

Although there has been much effort to improve each of these specific outcome variables (i.e. preoperative assessment, antithrombotic and antimicrobial prophylaxis, etc), therapeutic strategies have usually focused on unimodal interventions. One explanation for the paucity of data with a more global view of the postoperative period probably lies with the traditional orientation of various specialty groups. Thus surgeons have usually focused on surgically oriented postoperative complications, such as wound infection, shock and anastomotic dehiscence, and have ignored those complications being more "medical" in origin, such as those within the cardiac, pulmonary and cerebral systems. Anaesthetists have focused on those problems arising in the intraoperative or immediate post-anaesthetic period with emphasis on cardiovascular and pulmonary function, but may not see the majority of such morbidity because it arises in the later postoperative period in the surgical ward. Additional progress in postoperative outcome may require more attention to the pathogenesis of common postoperative complications and more focused attention on the later postoperative period (1–4 days) where the peak incidence of complications occurs.

The key pathogenic factor in postoperative morbidity, excluding failures of surgical and anaesthetic techniques, is the surgical stress response with subsequent increased demands on organ function. Much knowledge of the mediators of this response has accumulated in recent years with emphasis on biochemical and endocrine changes,[1] and several techniques have been developed which may attenuate these potentially undesirable responses (fig. 1), thereby providing a sound basis to avoid unnecessary development of postoperative organ dysfunction and associated morbidity. The development of pain-alleviating regimens which allow early ambulation, techniques to reduce nausea, vomiting and ileus, realization that early enteral nutrition is important for recovery and reduction of infective complications, and the use of well established antithrombotic and antimicrobial regimens therefore represent the basis for a global approach to perioperative care. However, an important limiting factor for this approach is inherited from surgical traditions not founded on scientific data. Examples are the inappropriate use of drains, nasogastric tubes, limited oral intake regimens, restrictions on mobilization, observational regimens, etc. A key question to be asked on each postoperative day, for each surgical procedure, is therefore "Why is the patient in hospital today ?" in order to provide continuous analysis and solution to those factors limiting early recovery and contributing to postoperative morbidity.

A rational approach towards control of the postoperative period is therefore multimodal intervention, as shown in figure 2. Before operation, detailed information about the accelerated stay programme must be provided, possibly including a videotape programme. Such detailed preoperative information has been demonstrated in itself to result in less pain and reduction of postoperative stay decades ago.[105] Stress reduction may be provided by currently available techniques (see above and fig. 1), and sufficient pain relief by currently available multimodal regimens. Most importantly, pain relief has to be used for early aggressive ambulation and enforced enteral nutrition to avoid the conventional postoperative functional impairment. Finally, in some high-risk patients, the use of growth factors or other anabolic supportive agents may be indicated.[13]

Unfortunately, controlled clinical studies of such a multimodal intervention to support an accelerated stay programme are not available. However, several small lines of evidence suggest that such a multidisciplinary effort may result in pronounced improvement in surgical outcome and reductions in morbidity and hospital stay after mastectomy,[67 68] carotid endarterectomy,[106] hip replacement,[107 108] colonic resection[29 103 104 109 110] and coronary bypass.[111 112] In this context it is noteworthy that the combination of laparoscopic-assisted surgery, extradural local anaesthetic, early nutrition and ambulation, and avoidance of opioids reduced hospital stay to 2 days without fatigue or cardiopulmonary, thromboembolic or infective complications in 15 high-risk patients (median age 81 yr) undergoing colonic resection.[103 109] In addition, regionalization of major surgical procedures to one hospital to increase experience and accelerate recovery may reduce costs and improve outcome.[113]

Reduced morbidity and accelerated convalescence

*Figure 2* Multimodal interventions towards control of the postoperative period

Multidisciplinary collaboration between patient, surgeon, anaesthetist, physiotherapist and surgical nurse represents an expansion of the more traditional "acute pain service" which merely serves to provide analgesia without taking part in the rehabilitation of the patient. We hypothesize that optimal results by postoperative "multimodal recovery intervention" may probably be best achieved by reorganization of the surgical wards into smaller postoperative "rehabilitation units" with a focus on early rehabilitation, nutrition and pain relief, and with a restrictive use of recovery-limiting procedures such as i.v. fluids, urinary bladder catheters, drains, tubes, etc. Such an approach may represent an important step to avoid the usual cascade to dependency in elderly hospitalized surgical patients, who are more sensitive to catabolic stress, immobilization, fluid changes and sensory deprivation.[60 114] Although accelerated stay programmes may reduce costs, these are not developed as enforced discharge programmes to save costs *per se*, but to take advantage of the improved postoperative functional status after such techniques, with early hospital discharge representing only an additional benefit.

## Future developments

Although major progress and improvements in surgical outcome may be expected by accelerated stay programmes, future research should be directed towards documenting such achievements from large-scale controlled studies or multi-institutional studies. In addition, the mechanisms of postoperative organ dysfunction within the first postoperative week should be explored further. In this context, further knowledge of the release mechanisms for the surgical stress response is required with information on the relative role of the different mediators which influence body organ functions. Presently, we have incomplete knowledge of which responses should be attenuated or stimulated, and which responses should be left unaltered. Nevertheless, the introduction of minimally invasive surgery, leading to reduction of catabolism, immunosuppression and other inflammatory responses with subsequent reduction of morbidity and convalescence, suggest that "stress-free anaesthesia and surgery" [11] may be valid. In this context, further developments in high technology surgery to reduce tissue injury will be promising. Furthermore, extension of research on biological modifiers[33] to improve postoperative immune function, on specific substrates such as glutamine and arginine to support gastrointestinal function and integrity and improve immunofunction,[13] and on various growth factors[13] are promising. Finally, it remains to be established if postoperative patients emerging from "stress free anaesthesia and surgery" with well-preserved organ function and who develop a later surgical complication because of a technical failure, are at reduced risk for subsequent development of multiorgan failure, sepsis, etc. This hypothesis deserves specific attention, as there is preliminary evidence that multiple physiological insults may be a mechanism for development of multi-system organ failure.[115] Thus development of multiple organ failure usually passes the phase of the more benign systemic inflammatory response syndrome (SIRS),[116,117] where the initial response to an elective operation may prime the body for development of detrimental consequences to a subsequent stimulus.

# Concentration and second gas effects: can the accepted explanation be improved?

B. KORMAN AND W. W. MAPLESON

**Summary**

During induction with high inspired concentrations of nitrous oxide, net uptake of gas produces a contraction in volume and a concentrating effect. In turn, this results in concentration and second gas effects. Most explanations of these effects are based on the common "rectangle" diagram devised by Stoelting and Eger and contain several inconsistencies which are explored here in order to produce a more accurate description. It is shown that in the standard diagram gas uptake is incomplete, there is ambiguity over functional residual capacity (FRC), equilibration with blood is inadequately represented and there is no representation of recirculation of anaesthetic. Compensation for loss of volume may be by means of an increased inspired ventilation, decreased expired ventilation or reduction in lung volume. Numerous accounts in the literature (including those based on the standard diagram) focus on the former mechanism at constant FRC. This has produced an unbalanced picture in which it is often implied that extra gas is routinely drawn into the lungs to replace that taken up. Significant compensation by this means cannot occur, for example when a constant volume ventilator is used. In discussing concentration and second gas effects, it is necessary to give a balanced view of the alternative mechanisms of compensation or to revert, as above, to a simple statement of the principle of conservation of volume. (*Br. J. Anaesth.* 1997; **78**: 618–625).

**Key words**
Anaesthetics volatile. Anaesthetics gases, nitrous oxide. Pharmacokinetics, uptake.Pharmacokinetics, nitrous oxide. Pharmacokinetics, lung.

In the early stages of anaesthesia with high inspired concentrations of nitrous oxide, large volumes of gas, of the order of 1 litre $\text{min}^{-1}$, are transferred from lungs to blood.[1] The disappearance of volumes of this magnitude manifests itself in various ways. As gas volume uptake commences, it is associated with one or more of the following: increase in inspired ventilation, decrease in expired ventilation or reduction in lung volume.[2] Simultaneously, "concentration" and "second gas" effects are detectable.[3–7] The precise relationship between these two types of phenomena remains confused in the literature and is often stated in terms that imply that the large volumes lost by uptake are always compensated for by large volumes of gas being drawn in automatically from the anaesthetic apparatus. In this article, the process of gas volume uptake is examined in a variety of circumstances, in some of which extra inflow provides only part or none of the compensation. In addition, most explanations of the concentration and second gas effects are based on the common "rectangle" diagram devised by Stoelting and Eger[7] and involve several anomalies—these are explored and a more comprehensive version of the diagram developed.

## Volume effects of gas uptake

In addition to being documented during anaesthesia with high inspired concentrations of nitrous oxide,[8] a reduction in functional residual capacity (FRC) occurs consistently in the anaesthetized patient under a wide range of unrelated conditions[9]: for example, during the use of halothane,[10] methoxyflurane[11] or isoflurane[12] in oxygen, or air–oxygen mixtures as the sole anaesthetic and during total i.v. anaesthesia (TIVA).[13] It is therefore reasonable to exclude a reduction in lung volume from the present discussion and limit our investigation to the effects of uptake on inspired and expired tidal volumes.

To simplify the discussion further, it is assumed that the patient is already anaesthetized by some other means, for example TIVA with 100% oxygen, the trachea intubated, connected to a non-rebreathing anaesthetic system and in a steady state at the time of introduction of nitrous oxide. Although differences exist between inspired and expired tidal volumes at steady state, owing to differences in the rates of exchange of oxygen and carbon dioxide, these are normally small and are also ignored, that is we assume a respiratory exchange ratio of 1.

Removal of gas volume by solution in lung tissue and blood may be reflected by a decrease in expired tidal volume or an increase in inspired tidal volume. Two extreme patterns are recognizable.[14–17] In one, the inspired tidal volume remains constant and equal

MAPLESON, DSC, FINSTP, FRCA (HON), Department of Anaesthetics and Intensive Care Medicine, University of Wales College of Medicine, Cardiff. Accepted for publication: January 20, 1997.

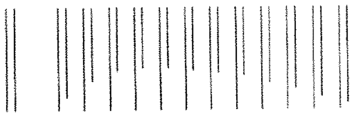
to its value during the control period. To compensate for the loss of gas volume, the expired tidal volume decreases. However, it does not remain the same from one breath to the next, reflecting the difference in uptake from breath to breath. Eventually, nitrous oxide uptake begins to decrease and expired tidal volume gradually returns towards its original level.

This sequence of events is illustrated in figure 1A, in which the first pair of vertical lines represents inspired and expired tidal volumes in the control period. Successive pairs of lines represent inspired and expired tidal volumes during later breaths at regular intervals thereafter, for example every minute.

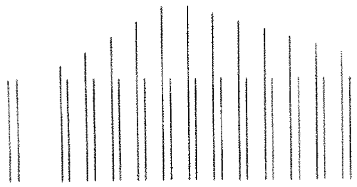
At the other extreme, we have a pattern in which expired tidal volume remains constant and equal to its value during the control period. Inspired tidal volume must therefore increase to compensate for the gas volume lost during the breath. Again, it does not remain constant from breath to breath but increases to a maximum and then gradually returns towards its control value, reflecting the time course of nitrous oxide uptake. This sequence of events is illustrated in figure 1B.

We refer to these as "constant inflow" and "constant outflow" situations. The term "constant" is used here in the sense that in one case, the inflow is constant from breath to breath and equal to its control value, while in the other it is the outflow that is constant from breath to breath and equal to its control value.

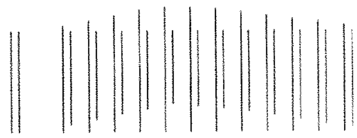
It is probable that neither extreme pattern is attainable clinically but a constant inflow is approximated by using a ventilator which cycles from inspiration to expiration after a preset volume has been delivered, and behaves as an atmospheric pressure generator during expiration, that is a constant volume ventilator.[14 16 17] A constant outflow is approximated during the use of a ventilator which includes a feedback loop based on end-tidal $P\text{CO}_2$,[18] and during spontaneous ventilation[14 16 17] if end-tidal $P\text{CO}_2$ is maintained constant and equal to its value in the control period.



A Constant inflow



B Constant outflow



C Intermediate situation

*Figure 1* Schematic representation of different respiratory patterns seen during gas volume uptake with high concentrations of nitrous oxide: (A) constant inflow, (B) constant outflow, (C) intermediate situation. Each pair of vertical lines represents inspired and expired tidal volumes, respectively, for a particular breath. The left-most pair in each case represents inspired and expired tidal volumes for a breath during the control period. The remaining pairs represent later breaths at regular intervals (for example every minute) after introduction of a high inspired concentration of nitrous oxide.

If the subject is connected, in the control period, to a ventilator which cycles from inspiration to expiration at a preset pressure and acts as an atmospheric pressure generator during expiration, then inspired tidal volume increases to replace the gas volume lost by uptake during inspiration and expired tidal volume decreases to compensate for the continued loss of gas volume during expiration.[17] This situation is illustrated in figure 1C and is intermediate between the constant inflow and constant outflow extremes.

Nitrous oxide exchange, in common with that of other anaesthetic gases, involves an equilibration process between gas and blood.[19] At equilibrium, the concentration in blood = $\lambda$ times the concentration in gas,[19] where $\lambda$ = blood–gas partition coefficient. Thus, if $\lambda$ is constant, the process obeys Henry's law, that is the dissolved concentration is proportional to partial pressure.[19] This is usually the case with inspired partial pressures of anaesthetics used clinically. In general terms we would therefore expect that the greater the inspired concentration of nitrous oxide, the greater the uptake and therefore the greater the difference between inspired and expired tidal volumes at any time during washin. This should apply irrespective of whether or not we are dealing with a constant inflow, constant outflow or intermediate situation.

## Concentration and second gas effects

At the same time as the difference between inspired and expired tidal volumes finds expression in one or other pattern, it is possible to demonstrate that the higher the inspired concentration of nitrous oxide, the more rapidly the alveolar concentration approaches the inspired concentration.[3-5] This has been termed the "concentration effect". Any other gas administered simultaneously, for example 1% halothane, is also associated with a more rapid increase in alveolar concentration than would have been the case in the absence of nitrous oxide. This has been termed the "second gas effect".[6]

The standard diagram[7] used to discuss gas exchange in these circumstances is shown in figure 2. The figure consists of three rectangles which are described as representing events in a hypothetical lung. In the absence of a more detailed description, we interpret this to imply that the rectangles are a schematic representation of successive approximations to end-inspiratory alveolar gas volume, that is $\text{FRC}+(V_\text{T}-V_\text{D})$. The hypothetical lung is filled initially with 80% nitrous oxide, 19% oxygen and 1% second gas. Uptake of half the nitrous oxide (without simultaneous uptake of oxygen or second gas) produces the situation shown in the middle rectangle, with a nitrous oxide concentration of

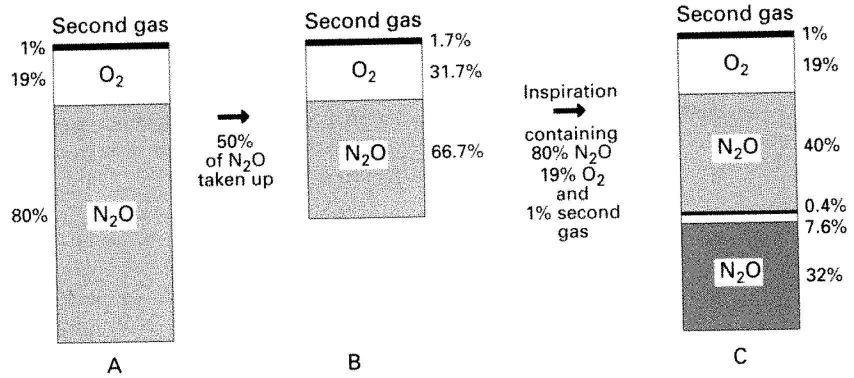


*Figure 2* Standard diagram of a hypothetical lung used to discuss gas exchange during nitrous oxide uptake. Percentages are of the total volume in each rectangle. Reproduced with permission from Stoelting and Eger.[7]

66.7%. To maintain lung volume, a further inflow of gas is necessary (B to C). This extra gas is shown having the same composition as in the first rectangle, and results in the concentration of nitrous oxide being increased further to 72%. The diagram or the associated explanation has appeared in numerous anaesthetic publications.[4 5 7 20–26]

Note that this treatment assumes that the second gas and oxygen are both insoluble (in the case of oxygen, a more realistic assumption[16] involves the exact replacement of oxygen uptake by carbon dioxide elimination, as assumed here).

Thus halving nitrous oxide initially present reduces its concentration from 80% to 72% instead of halving it to 40%. This argument has been used to explain the concentration effect by comparing this sequence with the situation where the initial nitrous oxide concentration is 1% and assuming again that half is taken up, but then replaced by almost pure oxygen,[5] so that nitrous oxide concentration is indeed almost exactly halved to 0.505%.

Meanwhile, the second gas which starts at a concentration of 1%, increases in concentration to 1.7% in the middle rectangle (a concentrating effect) and finally reaches 1.4% after being diluted by the increased inspiratory ventilation necessary to maintain lung volume (B to C). In figure 2, the solubility of the second gas has been assumed to be zero, and the increase in its concentration is seen to be caused by the concentrating effect. At the other extreme, if the second gas is very soluble, A to B takes the concentration from 1% towards zero, so that the concentrating effect associated with the uptake of nitrous oxide is much reduced. However, from B to C, the extra inflow restores the concentration of the second gas to at least 0.4%, so that the extra inflow seems to be more important.

Figure 2, as drawn, can also be interpreted as applying to a second gas which is soluble but with which the patient has been fully equilibrated before the carrier gas is changed from oxygen to a nitrous oxide–oxygen mixture. Thus there is little uptake of the second gas from A to B and its concentration is increased (although not quite to 1.7%) by the concentrating effect of the large uptake of nitrous oxide.

These comparisons have formed the basis of a hypothesis[7] that the further the second gas is from equilibration, the more its solubility determines which mechanism predominates—concentrating effect or extra inflow.

Note that the choice of the terms "concentration effect" and "concentrating effect" is rather unfortunate. The concentrating effect is an effect of uptake on concentration, whereas the concentration effect is an effect of concentration on uptake, that is on the rate of approach to equilibrium.

## Deficiencies in the standard gas-exchange diagram

It may be shown that there are four deficiencies in figure 2: (1) gas uptake is incomplete; (2) there is ambiguity over FRC; (3) equilibration with blood is inadequately represented; and (4) there is no representation of recirculation of anaesthetic.

These deficiencies are now considered in turn.

### INCOMPLETE UPTAKE

Although the gas present in the left-hand rectangle has been equilibrated in the sense that half the nitrous oxide has been removed, that in the extra inspired ventilation has not, a situation that is incompatible with the known behaviour of inert gas exchange.[19] This deficiency can be rectified by allowing half the nitrous oxide in the extra inspired ventilation to be taken up by blood. If we follow the reasoning used in the diagram, this results in a reduction in volume so that a further inspired ventilation is necessary and also has to be equilibrated. The process is depicted in figure 3, and continues for an infinite number of successively smaller steps to completion with a total uptake of nitrous oxide, and therefore a total extra inflow of inspired mixture, which is greater than that shown in figure 2, but still finite (267 ml instead of 160 ml).

The final concentrations of each agent may be deduced by inspecting each of the equilibrated portions, that is parts B, D, and F of figure 3 from which it can be seen that the final gas consists of an infinite number of portions each comprising 66.7% nitrous oxide, 31.7% oxygen and 1.7% second gas, so that this must also be the composition of the final gas mixture, that is the extra inflow is not associated with dilution and does not oppose the concentrating effect, as suggested previously. Note also that the representation of gas exchange as a stepwise process,

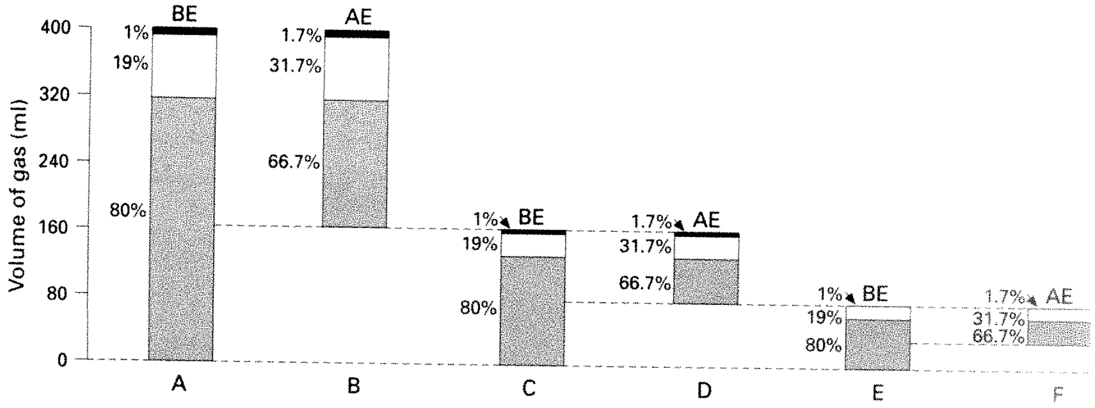

*Figure 3* Multi-step method of completing nitrous oxide uptake (stippling=nitrous oxide, white=oxygen, black=second gas). A: 400 ml of gas are contained initially in the "lung". B: The situation after half the nitrous oxide has been absorbed. C: Extra gas is brought in to replace the absorbed nitrous oxide. D: Half the nitrous oxide is absorbed from the extra gas. E: This necessitates a further inflow of gas from which half the nitrous oxide is removed (F). The process is continued until uptake is complete. The gas in the "lung" then consists only of equilibrated portions, that is B+D+F+... BE=Before equilibration; AE=after equilibration. Total uptake of nitrous oxide, and therefore the total extra inflow of inspired mixture, is finite (267 ml) but greater than in figure 2 (160 ml).

as shown in figures 2 and 3, is purely schematic; in reality, absorption and replacement occur concurrently.

## AMBIGUITY OF FRC

So far, figure 2 has been accepted as representing the events in the lungs as stated by the original authors.[7] This statement is now examined further.

The "lung" originally contains 80% nitrous oxide, 19% oxygen and 1% second gas. But this is also the composition of the inspired gas mixture (the "extra inspired ventilation" in the third rectangle). Such a situation applies only at the end of washin. However, when equilibration is complete, no further gas uptake occurs, contradicting the requirement that half the nitrous oxide be taken up.

An alternative interpretation is to regard the first rectangle in figure 2 as inspired tidal volume entering the lungs. The middle rectangle then represents what is left of this tidal volume after half the nitrous oxide has been taken up. There is, however, a problem with this interpretation, namely that when the inspired tidal volume enters the lungs and mixes with the gas in the FRC, the constituents of alveolar gas should appear in the expired tidal volume. For instance, if the subject had been breathing 100% oxygen during the control period, as assumed here, the concentration of oxygen in the expirate would be expected to be greater than shown in figure 2B.

This leaves us with a final interpretation of figure 2 in which the diagram is taken to represent an inspired tidal volume directly equilibrating with blood in the absence of FRC. Although this is an extraordinary assumption, it serves a useful purpose at this point in that it simplifies discussion of the volume effects of gas uptake and maximizes those effects by eliminating dilution of the inspired nitrous oxide in FRC.

Assuming zero FRC and uptake of half the nitrous oxide, we can now draw diagrams for the constant inflow and constant outflow situations. This has been done in figure 4. The first pair of rectangles represents the constant inflow case; these are identical to the first two rectangles in figure 2. An inspired tidal volume of 400 ml (fig. 4A), comprising 80% nitrous oxide, 19% oxygen and 1% second gas loses half of the nitrous oxide (160 ml) as a result of gas uptake and results in the expired tidal volume shown in figure 4B. The second pair of rectangles represents the constant outflow case. To maintain expired tidal volume constant and equal to 400 ml, the inspired volume has to be sufficiently in excess of 400 ml to provide for the uptake of half the nitrous oxide (267 ml) that takes place in going from figure 4C to figure 4D. Note that the total uptake in the second pair of rectangles is equal to the sum of the parts in figure 3.

## INADEQUATE EQUILIBRATION WITH BLOOD

In figure 4, the composition of the expired gas is the same, whether it is the inflow or outflow that is kept constant. This occurs because of the stated condition that "half the nitrous oxide be absorbed".[7] In reality, the fraction of nitrous oxide absorbed is not fixed but depends on equilibration between gas and blood, in accordance with Henry's law.[19] When this is allowed for, we obtain the situation shown in figure 5. Here we have assumed for convenience that each breath equilibrates with 400 ml of blood. $\lambda$ for nitrous oxide has, for simplicity, been assumed to equal 1 so that the concentrations of nitrous oxide must be the same in gas and blood at equilibrium. It has also been assumed that recirculation of anaesthetic has not yet occurred so that initially the blood contains no nitrous oxide. As before, the second gas and oxygen are assumed to be completely insoluble.

It can be seen that, after equilibration, constant inflow and constant outflow patterns are associated with different concentrations of each gas. In particular, in the constant outflow case, a larger volume of nitrous oxide enters the blood than in the constant inflow case (267 ml *vs* 221 ml), although this represents a smaller fraction (40% *vs* 55.3%) of an increased inspired volume (667 ml *vs* 400 ml). As a result, the concentration in blood is greater in the constant outflow case (66.7 ml% *vs* 55.3 ml%), that is equilibration is more advanced.

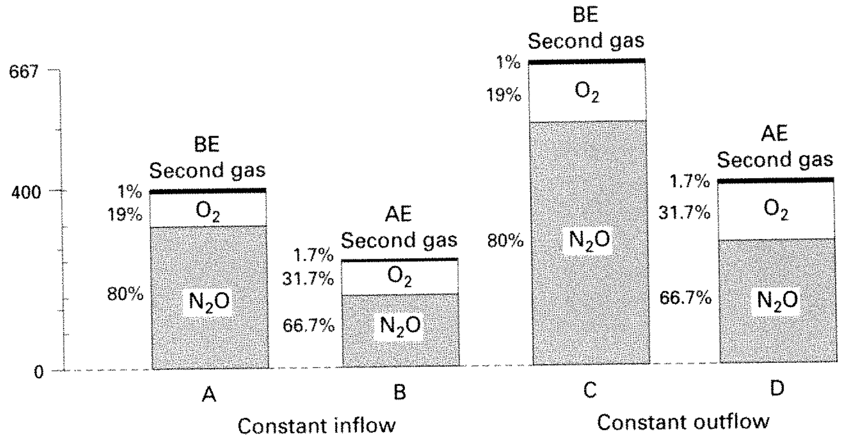

*Figure 4* Constant inflow and outflow cases before and after uptake. A–B: Inspired tidal volume is kept constant and equal to 400 ml. C–D: Expired tidal volume is kept constant and equal to 400 ml. BE=Before equilibration; AE=after equilibration. The gradations on each side of the *Y*-axis occur at intervals of 20% of the inspired tidal volume for each case, that is at intervals of 80 ml for the constant inflow case and 133.3 ml for the constant outflow case.

Each of the three gases in figure 5 has been subjected to a concentrating effect. To see this in relation to nitrous oxide it is helpful to distinguish, before equilibration, between nitrous oxide destined for absorption and that destined to remain unabsorbed. This has been done by using different densities of stippling. Thus the black areas in figures 5A and 5C represent nitrous oxide destined to be absorbed. The unabsorbed nitrous oxide is seen to increase its concentration from 24.7% to 55.3% in the constant inflow case and from 40% to 66.7% in the constant outflow case. The increase in concentration of each of the three gases is equal to the quotient of the initial and final gas volumes.

Concentration and second gas effects are both demonstrable in terms of figure 5. The second gas effect is obvious. Its cause, a concentrating effect associated with absorption of nitrous oxide, is also obvious. To demonstrate the concentration effect it is necessary to consider what would be different with a lower inspired concentration.

If the inspired gas had contained only 1% nitrous oxide (4 ml in the constant inflow case) then after equilibration with blood there would be 2 ml of nitrous oxide in 400 ml of blood (0.5 ml%) and 2 ml in 398 ml of gas (0.502%). Thus there would be negligible contraction of volume and a negligible concentrating effect. The result would be almost identical in the constant outflow case. In these circumstances, blood comes into equilibrium with only half the inspired concentration. On the other hand, at a high inspired concentration of nitrous oxide (80% in fig. 5), there is a marked contraction in volume, a marked concentrating effect and blood

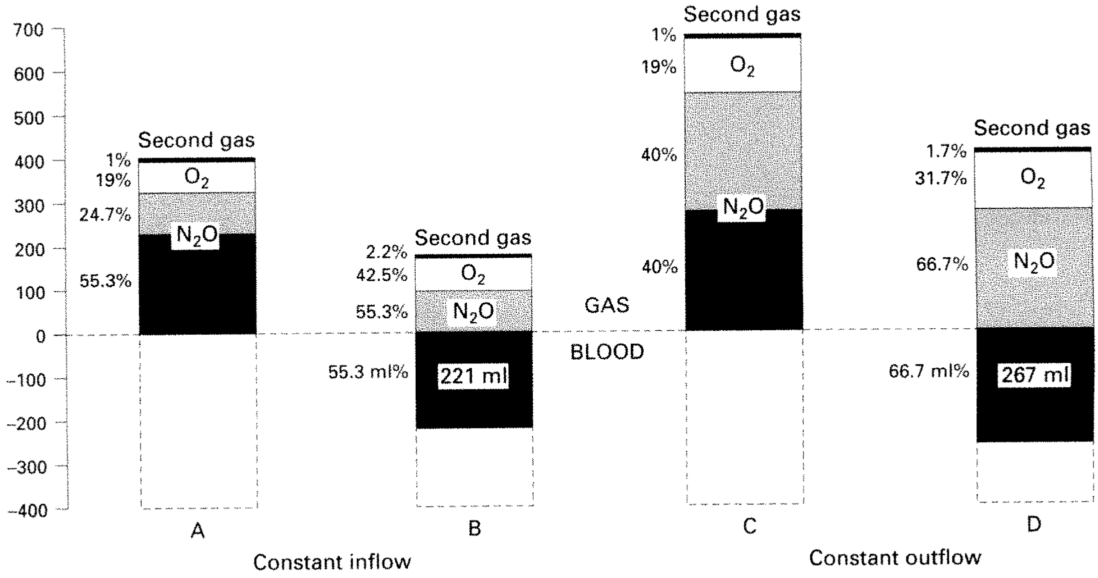

*Figure 5* Constant inflow and outflow cases before and after equilibration with blood. A–B: Inspired tidal volume is kept constant and equal to 400 ml. C–D: Expired tidal volume is kept constant and equal to 400 ml. The *X*-axis represents the gas–blood interface across which equilibration occurs. In A and C, the area outlined by the dashed line on the blood side of the gas–blood interface represents the 400 ml of blood, initially free of nitrous oxide, to be equilibrated with gas. For simplicity, λ has been set to 1. The black area=nitrous oxide destined for absorption, the stippled area=nitrous oxide destined to remain unabsorbed. The volumes of gas in A, B, C and D are 400, 179, 667 and 400 ml, respectively.

comes into equilibrium with much more than half the inspired concentration: (55.3/80)×100=69% for the constant inflow case and (66.7/80)×100=83% for the constant outflow case. Thus a high inspired concentration leads to uptake of a larger fraction of the inspired volume and hence to a more rapid approach to equilibrium, especially in the constant outflow case, but even when conditions are such that Henry's law leads to half the nitrous oxide being taken up (C to D in fig. 5), the final concentration is 66.7%, not 72%, as in figure 2.

### NO REPRESENTATION OF RECIRCULATION OF ANAESTHETIC

In figure 2, there is no representation of venous return and the associated recirculation of anaesthetic. Thus figures 2–5 each represents a "snapshot" of events before recirculation of anaesthetic. These deficiencies may be rectified and FRC incorporated simultaneously by reverting to a comprehensive computer model of anaesthetic uptake. When this is done, for example with the electrical analogue of Mapleson, it can been shown[16] that the constant outflow case is indeed always at a more advanced stage of equilibration during washin.

It is also possible to incorporate a non-zero FRC and recirculation of anaesthetic into the rectangle diagram. This has been done for the constant inflow case in figure 6 which is drawn for some arbitrary point during washin.

The diagram follows the same sequence as the mathematical model from which the existence of the concentration effect was first predicted,[3] that is instantaneous inspiration (fig. 6A) followed by complete mixing between the inspired tidal volume and the gas in FRC (fig. 6B), followed by equilibration with blood (fig. 6C), followed by separation into FRC and gas destined for instantaneous expiration (fig. 6D).

Using similar arguments to those used in relation to figure 5, it is possible to demonstrate the occurrence of concentration and second gas effects. Comparing figure 6 with the constant inflow case in figure 5, it can be shown that the reduction in gas volume for the breath decreases from 221 to 120 ml in absolute terms and from 55.3% to 5% as a percentage of the initial gas volume. This occurs because dilution of nitrous oxide in FRC and appearance of gas in the venous return both act to reduce the pressure gradient favouring nitrous oxide absorption. Accordingly, the concentrating effect is significantly reduced so that both concentration and second gas effects are reduced in magnitude, for example 35 ml% nitrous oxide in blood in figure 6 instead of 55.3ml% as in figure 5, and 0.614% second gas in the gas phase instead of 2.2%.

Of course, the values 0.5%, 30%, 69.5% in FRC and 5ml% in blood in figure 6A are all assumed. But whatever they are in practice at the beginning of a particular breath, a similar argument applies. The same is true if we use the constant outflow case and also if FRC is allowed to change in figure 6D instead of, or as well as, tidal volume. This last result should surprise no one as the principle of conservation of volume requires only that in the presence of net gas uptake, there must be a contraction in volume and a concentrating effect; maintaining lung volume is a convenient assumption in both the constant inflow and constant outflow models and is implied in the current treatment by the steady state condition with TIVA and 100% oxygen. Explanations of the concentration and second gas effects based on the relative solubilities of nitrous oxide and nitrogen merely restate the principle of conservation of volume in terms of the contributions of individual gases.

## A one-sided picture of gas exchange

An unfortunate consequence of the widespread use of

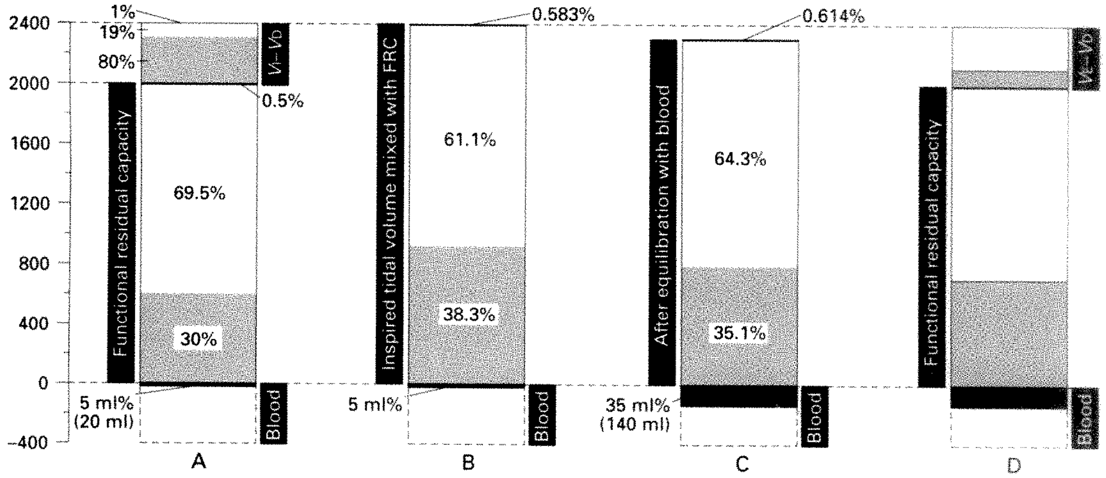

*Figure 6* Constant inflow case with FRC and recirculation of anaesthetic. Single respiratory cycle during washin of nitrous oxide. An inspired mixture of 1% second gas (black), 19% oxygen (white) and 80% nitrous oxide (light shading) is used with a non-rebreathing system. The *Y*-axis shows the volume of gas or blood (ml). A: From top down, 400 ml of inspired gas mixture ($V_I - V_D$); FRC 2 litre comprising 0.5% second gas, 69.5% oxygen and 30% nitrous oxide; 400 ml of blood for equilibration containing 20 ml of recirculated nitrous oxide (black area). B: After complete mixing of inspired gas with FRC. C: After equilibration of gas with 400 ml of blood ($\lambda = 1$ for nitrous oxide and 0 for oxygen and the second gas). Dissolved nitrous oxide is shown as black. D: From top down, expired alveolar tidal volume ($V_E - V_D$)=280 ml, FRC (still 2 litre) and blood, after equilibration.

figure 2 in texts on anaesthetic uptake is the implication that further gas is sucked routinely into the lungs during induction with high inspired concentrations of nitrous oxide. This concept has been expressed in various terms by different authors.[2,4,6,20,22–35] Although some accounts have not appealed to this phenomenon (e.g. Nunn[9]), or have used diagrams other than the standard diagram to help explain concentration and second gas effects (e.g. Hull[2]), the large number which have done so have conferred legitimacy on the underlying proposition.

There are three important aspects of these explanations with the emphasis varying from author to author: (i) gas is automatically drawn into the lungs to replace the volume loss caused by uptake, (ii) this is because otherwise lung volume would shrink, (iii) replacement is inevitable and beyond the control of the anaesthetist.

The problem with these descriptions is that they are limited in scope and fail to consider the alternative volume effects of gas uptake. Thus we can see from figure 1 that when authors write of an extra inspired ventilation[3,4,7,26] they are actually referring to the constant outflow case, in which an extra ventilation is readily identifiable. However, this requires not only constant lung volume but also constant expired ventilation, a point that is not usually stated explicitly.

Moreover, the implication that the anaesthetist has no control over the influx of this extra gas is demonstrably incorrect.[17] The anaesthetist decides whether or not respiration is to be spontaneous, and the type of ventilator to be used in the latter case. Ultimately, it is therefore the anaesthetist who decides whether there is an extra inspired ventilation, decreased expired ventilation or a combination of the two. Note also that in cases where a constant volume ventilator has been used,[7,29,31] extra inspired ventilation should never have come into consideration.

The preoccupation with the constant outflow case means that quantitative problems have often been cast solely in these terms to the exclusion of all other possibilities. The solutions obtained have not necessarily been universally applicable. For example, the concentration effect can be mimicked mathematically by a reduction in solubility.[16] One report of this property[36] was limited to the constant outflow case and overlooked an alternative mathematical expression that applies in the constant inflow case. Expressions for both cases were deducible in the original demonstration of this property.[16]

## Balancing the ledger

The merit of the standard diagram (fig. 2) is that it gives some indication of how the concentration and second gas effects arise, when previously they emerged only from the correct application of the principle of conservation of volume in a computer program[3,4] or in an electrical analogue.[16] As such the diagram has probably helped innumerable students to gain some insight into these effects.

The disadvantage of the standard diagram is that numerous anomalies appear when it is examined closely: implied assumption of zero FRC; omission of uptake from the additional inspired gas; absence of any consideration of the process of equilibration with blood, and hence of the influence of recirculation; and restriction to the case of constant FRC, constant outflow.

For teaching purposes, simple qualitative models are often ideal, as long as they do not materially mislead the student. Figure 2 implies that an extra inflow of gas must be associated with a diluting effect, a proposition that is challenged in figures 3 and 4. The extent to which it is worth introducing the successive corrections contained in our figures 3–6 is a matter of judgement, although we believe that they should be mentioned. In addition, it seems regrettable that most of the accounts of the concentration and second gas effects based on figure 2 deal only with the constant outflow case at constant FRC. Although two authors[2,21] make some passing reference to alternative circumstances such as the constant inflow case, their detailed account is solely of the constant outflow case, typical of spontaneous breathing, which tends to reinforce the impression of the inevitability of extra gas being "sucked in" to replace that taken up. Indeed, one of the present authors must plead guilty to this in one of his publications![37]

To the best of our knowledge, figures 3–6 have not appeared previously in the anaesthetic literature. We believe that they extend the understanding of the concentration and second gas effects. Figure 6 certainly mirrors the steps of Eger's mathematical model more accurately than figure 2 but a second diagram is then needed to demonstrate the constant outflow case. As a bare minimum, we believe that explanations should include the statement that the net uptake of gas produces a contraction in volume which inevitably leads to concentration and second gas effects, regardless of whether compensation for uptake is by extra inflow, reduced outflow, decreased lung volume or a combination of the three.

# CORRESPONDENCE

## Sternomental distance as predictor of difficult laryngoscopy

Sir,—I should like to comment on the article of Ramadhani and colleagues[1] which described the use of measurement of sternomental distance in the prediction of difficult laryngoscopy. The sensitivity and specificity of the test, using different "cut-off" or threshold values for sternomental distance, were calculated. The authors stated that "using discriminant analysis, a sternomental distance of 13.5 cm or less was calculated as the most accurate cut-off point for discriminating between difficult (grades III and IV) and easy (grades I and II) laryngoscopy". There is, however, no rigid statistical way in which cut-off values can be determined in diagnostic tests involving continuous quantitative data. Such values depend on the specific nature of the test and are usually determined by clinical consensus, based on whether or not an excess of false positives is less important than an excess of false negatives, or vice versa.[2]

In this study, the prevalence of difficult laryngoscopy was 0.035 (3.5%). This can be interpreted as the probability that a patient will present difficulty at laryngoscopy before the test is carried out, and so it is known as the prior probability. Similarly, the prior probability that the patient's trachea will be easy to intubate is 0.965. The positive and negative predictive values are the revised estimates of these probabilities in patients who are positive and negative to the test, and are known as the posterior probabilities The difference between prior and posterior probabilities at any given cut-off level is one way of assessing the usefulness of a test.[3] For the cut-off point of 13.5 cm, being test positive only increases the prior probability from 0.035 to a posterior probability of 0.076. In other words, being test positive only increases a patient's probability of being a difficult laryngoscopy by approximately 4 percentage points. Similarly, being test negative increases the prior probability of 0.965 to a posterior probability of 0.984, which represents an increase in probability of an easy laryngoscopy of only 1.9 percentage points.

More importantly however, before the fine details of optimum cut-off values are considered, it is imperative to evaluate the diagnostic accuracy of the test. Ramadhani and colleagues almost did this when they constructed a receiver operating characteristic (ROC) curve (a plot of sensitivity against (1−specificity) for each of a range of cut-off values), but they failed to calculate the area under this curve. It is the area under the ROC curve which determines the diagnostic accuracy. A "perfect" test is one whose ROC curve runs up the abscissa to a sensitivity value of 1, and then along a line parallel to the ordinate. The area under such a curve equals 1. A totally worthless test is one whose ROC curve runs along the line of identity. The area under such a curve equals 0.5.

I have calculated the area under the ROC curve of Ramadhani and colleagues to be approximately 0.71 (Simpson's method). What is also missing from Ramadhani and colleagues' data are the standard errors of the measured sensitivities and specificities. These are both binomial proportions taken from populations whose proportions are $p_{\text{sens}}$ and $p_{\text{spec}}$. The standard errors of these sample proportions are given by:

$$\text{standard error} = \sqrt{\frac{p\,(1-p)}{n}}$$

where $p$ can be estimated from the sample proportion (i.e. the sample specificity or sensitivity).[4]

Figure 1 shows the ROC curve re-drawn from the authors' data with the appropriate confidence intervals (+/− $t_{0.05}$ standard errors). These confidence intervals define the axes of the spindle shaped areas which contain the population data with 95% confidence. One such shape is shown for a sternomental distance of 13.5 cm. If the lowest points of these spindles are plotted, this creates the ROC curve seen in figure 2. This represents a "worst-case" ROC, but is within the 95% confidence limits of the data. The ROC curve in figure 2 follows closely the line of identity and the area under it is approximately 0.535. This implies that, from these data at least, measurement of sternomental distance as a predictor of difficult laryngoscopy may have a diagnostic accuracy approaching worthlessness.

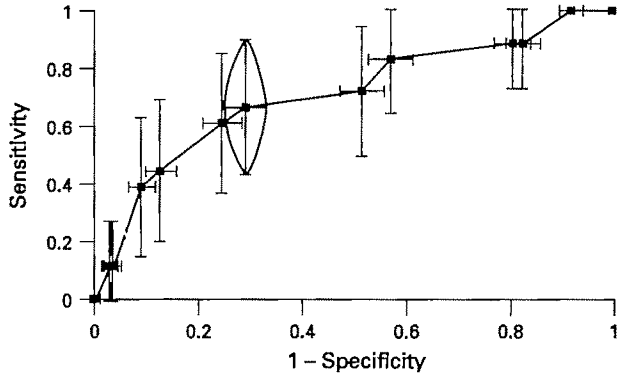

*Figure 1* Receiver operating characteristic (ROC) curve for sample data, with confidence intervals.

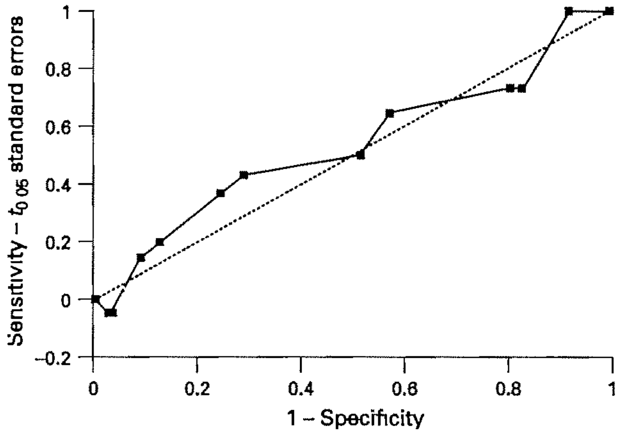

*Figure 2* Modified receiver operating characteristic (ROC) curve with data points from extremes of confidence intervals. Broken line=line of identity.

4. Bland M. *An Introduction to Medical Statistics*, 2nd Edn. Oxford: Oxford University Press, 1995.

Sir,—Thank you for the opportunity to reply to Dr Farmery's letter.

One of the statistical problems was to develop a rule, based on sternomental distance, that could be used to discriminate between easy and difficult laryngoscopy. One way of doing this statistically is by performing discriminant analysis. In our study, a linear discriminant function, $l=b\times\text{SMD}$ (sternomental distance) was calculated using parametric methods (i.e. using a measure of generalized squared distances, based on covariance matrices, but also taking into account the prior probabilities of the groups). In order to use $l$ for allocating patients to one of two groups, we had to specify a cut-off point, such that a patient can be assigned to one group if his score exceeds this cut-off value and to the other group if it does not.[1] It was shown that for a cut-off point of 13.5 cm the misclassification rate was minimized.

Although the ROC curve in this study was used mainly to illustrate the predictive properties of each of the cut-off levels, we agree with Dr Farmery that the area under the curve would have been useful for assessing the diagnostic accuracy.

Using the Trapezoidal method, we calculated the area under the ROC to be 0.71. The area under the "worst-case" ROC, as illustrated by Dr Farmery (i.e. plotting sensitivity $-t_{0.05}$ SE against $1-$specificity), was calculated to be 0.596. (Note that the appropriate way to estimate confidence intervals for proportions is by $p \pm N_{1-\alpha/s}$ SE, and not using the $t$ distribution as suggested by Farmery.[2]) Although this value is quite low, it should also be mentioned that the area for the "best-case" ROC (using sensitivity$+N_{1-\alpha/2}$ SE) was 0.828, which can be considered very good. Based on this interval, which clearly excludes an AUC of 0.5, we cannot, on statistical grounds, reject the measurement of sternomental distance as a worthless predictor of difficult laryngoscopy. In addition, we would again like to reiterate the message of our article which was that sternomental distance could not be used on its own as a sole predictor of difficult laryngoscopy but should be added to a series of simple preoperative tests.

## Neuromuscular block in children

Sir,—In her editorial, Dr Hunter states that anaesthetists should question if they are using too much neostigmine and suggests that a reduced dose of 1.25 mg may be preferable in adults.[1] However, there is no mention of the incidence of postoperative residual curarization (PORC). While this is rare in children,[2] PORC occurs in up to 48% of patients with agents such as pancuronium and curare.[3,4] With the introduction of atracurium and vecuronium, the incidence of PORC is reduced, but is still a significant problem. Myself and my colleagues recently demonstrated that PORC affects 12% of adult patients after a bolus of one of these two drugs and occurs in 24% after infusions.[5] Moreover, we demonstrated that even those patients in whom a peripheral nerve stimulator was used during operation did not have a reduced incidence of PORC. Other workers have also shown PORC to occur in 9% of patients who had received vecuronium.[6]

Given the premise that PORC still occurs commonly even with intermediate acting non-depolarizing agents, I question the rationale and evidence for reducing the dose of neostigmine in adults. PORC may result in hypoventilation and inability to protect the airway, in addition to being subjectively unpleasant for conscious patients. Moreover, because side effects of neostigmine are relatively minor compared with the potential serious adverse sequelae of PORC, I would urge caution in reducing the standard dose of neostigmine until the safety of this has been confirmed.

6. Bevan DR, Smith CE, Donati F. Postoperative neuromuscular blockade: a comparison between atracurium, vecuronium, and pancuronium. *Anesthesiology* 1988; **69**: 272–276.

Sir,—Thank you for the opportunity to reply to Dr Fawcett's letter. As I expressed in my editorial,[1] the need for caution when deciding not to use an anticholinesterase to antagonize residual neuromuscular block is paramount. This is particularly so if aminosteroids are used: I believe one should not consider omitting the anticholinesterase after these drugs. The increased incidence of residual curarization after the use of the longer acting agents, pancuronium and tubocurarine, is one reason to select atracurium or vecuronium, even for long surgical procedures.

When using the benzylisoquinoliniums, I stressed the necessity to monitor neuromuscular block throughout anaesthesia if an anticholinesterase is to be omitted. The weakness of Dr Fawcett's argument is that in his retrospective study,[2] some of the patients were monitored for the first time in the recovery room. Even in the patients who were monitored peroperatively, the clinical practice of the anaesthetist, as much as the neuromuscular blocking drug, could be at fault in preventing full recovery from neuromuscular block before extubation. For instance, if the anticholinesterase is given before recovery from block is established, or if time is not allowed for the anticholinesterase to act, recovery may be inadequate on arrival in the recovery room. Obviously, there is a need for a large prospective study of PORC in patients who have been given varying doses of anticholinesterase at different degrees of recovery from block induced by varying neuromuscular blocking drugs. But the use of smaller doses of neostigmine has been demonstrated repeatedly to produce good recovery after atracurium and vecuronium, provided the anticholinesterase is not administered until 20% recovery of the first twitch of the train-of-four response. The time to full recovery after administration of neostigmine is longer than many anaesthetists realize, at least 7–10 min.[3,4]

I suspect we would agree that continuous neuromuscular monitoring is essential throughout anaesthesia and until tracheal extubation, whether or not an anticholinesterase is used. When an anticholinesterase is given, it should not be administered until recovery is well established (at least two twitches of the train-of-four response are present) for full recovery from block to be reliably obtained. This is particularly pertinent when repeated bolus doses or a continuous infusion of a neuromuscular blocking agent is used.

## Cutting paediatric tracheal tubes—a potential cause of morbidity

Sir,—We wish to describe a critical incident that occurred at our institution recently. A child of 13 months required prompt tracheal intubation and ventilation as part of the management of acute meningitis. After induction of anaesthesia the trachea was intubated easily with a size 3.5 mm internal diameter tracheal tube, a single use Blue Line tracheal tube (SIMS Portex Ltd

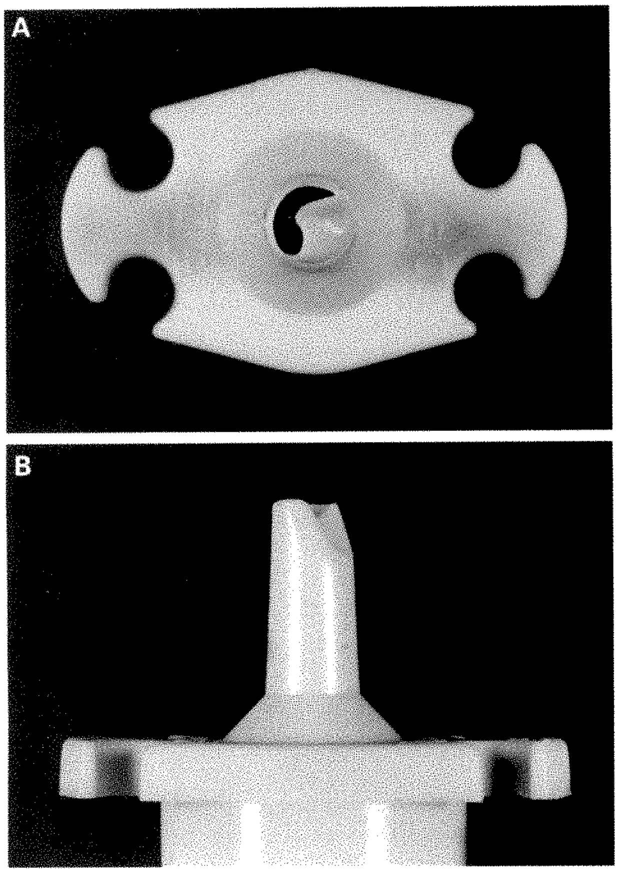

*Figure 1* End and side views of the Portex connector showing partial occlusion.

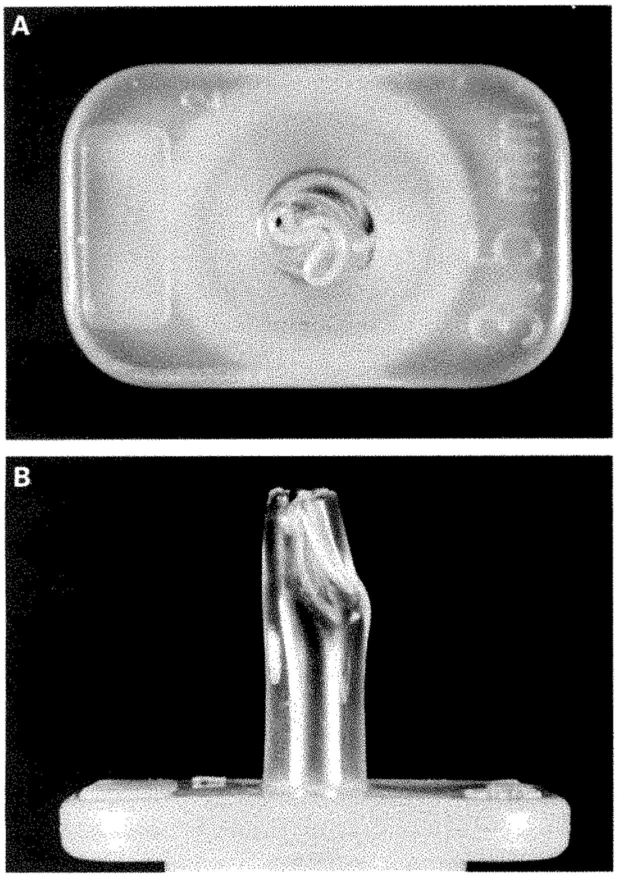

*Figure 2* End and side views of the Mallinckrodt connector showing complete occlusion.

Hythe, England) which had been cut to 14 cm immediately before use. Although the child's lungs could be ventilated, a 4-French gauge endobronchial suction catheter could not be passed through the tube to aspirate pulmonary secretions. The tube was therefore changed. A Contour tracheal tube (Mallinckrodt Medical UK Ltd) of the same size, also cut immediately before use, was inserted in its place. On this occasion we were unable to ventilate the child's lungs. It rapidly became apparent that this tube was completely occluded and it too was changed. This occurred uneventfully.

On subsequent detailed inspection it was discovered that both tubes had suffered the same complication (see figs 1, 2). The plastic 15-mm connector, while being inserted into the cut tube by an experienced operating department assistant (ODA), had buckled inwards occluding its distal lumen. This occlusion was very difficult to see from routine external inspection of either tube, which is why the problem was not detected when the equipment was checked rapidly before use by the anaesthetist and the ODA.

Portex Ltd and Mallinckrodt Medical are unaware of any previous description of this problem occurring in standard sized connectors and are investigating the respective tubes for manufacturing defects. A similar problem has been described only in 8.5-mm Minilink connectors for 3.0-mm and 4.0-mm Portex Blue Line tracheal tubes[1] when the problem was blamed on excessive twisting during re-insertion of the connector.

In this case the clinical urgency of the situation resulted in the tubes being checked less thoroughly than normal, and probably also accounted for any excessive force that may have been used in re-inserting the connectors. It is therefore important to recognize that the situation could have been avoided entirely by using an un-cut tracheal tube. While texts on the management of paediatric emergencies still provide formulae for calculating the length to which tracheal tubes should be cut,[2] we feel that in the emergency situation the practice of cutting tracheal tubes immediately before use should be discouraged. It not only takes longer but, as this incident demonstrates, is also a potential source of disaster.

## Lead by example

Sir,—I was recently unfortunate enough to require a general anaesthetic myself. I was admitted to a teaching hospital with a prolapsed intervertebral disc and was to undergo a microdiscectomy. As the second patient on the list, I was seen 30 min before going to theatre, by a first-year specialist registrar, who was in the first week of his neurosurgery attachment. He was uncertain of his supervising consultant's proposed postoperative analgesia plans and was clearly intimidated in talking to another anaesthetist.

The consultant was still transferring the previous patient to recovery when I arrived in theatre and had asked the trainee to proceed. A dose of fentanyl was followed rapidly by thiopentone and a neuromuscular blocking agent, and the next thing I remember was a gagging sensation as the tracheal tube snagged on my arytenoid cartilages before entering the trachea. The combination of sensory input and no motor response was difficult to describe, but it was certainly unpleasant, and I am sure that for someone without any anaesthetic knowledge, would have been terrifying.

Despite mentioning this occurrence to the ward nurses after operation, I did not see an anaesthetist again before my discharge 2 days later. This experience has highlighted one or two areas of training that I feel need to be addressed.

Where trainees are with a consultant for a teaching list, it is not unreasonable for the trainee to be asked to see the patients for the remainder of the list, when the first patient is on the operating table. In many specialties, it is not possible to publish a list the day before, as a major part of the workload may be emergencies. However, if a trainee is sent to see patients, it is vital that they know what the consultant is proposing to do, and how it is to be undertaken. Consent for anaesthetic must be as informed as consent for surgery. Detailed explanations of the anaesthetic procedures and their associated risks must be provided. If the consultant does not provide sufficient information, the trainee should seek further clarification before seeing the patient. If trainees do not feel confident that they can explain the procedure adequately to the patient or are not aware of the potential complications of the procedure to be undertaken, they should request a joint visit with the consultant to see how the explanation should be given. In these litigious days, uninformed consent can be the basis for many legal actions. Very few trainees ever see consultants inform their patients about anaesthetic procedures, risks or complications, and this is an area which could be improved.

My second point concerns the practice of postoperative visits by anaesthetists As a trainee, I was taught that the list had not finished until patients had been reviewed on the ward after their operations Sadly, postoperative visits to NHS patients are becoming less common. A recent survey in Bath revealed that only 14% of NHS patients were seen on the ward after operation by an anaesthetist, even though the proportion approached 90% in the private sector. The main reason cited for this was that sessions funded for postoperative visiting in the NHS were being taken up by other clinical and administrative duties, whereas in the private cases, a postoperative visit resulted in an additional payment.

Trainees pick up the habits of their trainers. If they see cosultants neglecting their responsibilities, and not visiting patients after the list has finished, or the following day, it is not surprising that postoperative visits are becoming a thing of the past, with very little perceived value to managers. If the present trend continues, will preoperative visits be the next victim?

# CHANGE IN EDITORIAL ARRANGEMENTS

From June 1, 1997, all new manuscripts and correspondence to the Editor of the *British Journal of Anaesthesia* should be addressed to:

Dr J. M. Hunter
Editor-in-Chief
*British Journal of Anaesthesia*
Department of Anaesthesia
Royal Liverpool Hospital
The Duncan Building
Daulby St
Liverpool L69 3GA
Tel./Fax: (0151) 706 4005.

*British Journal of Anaesthesia* 1997; 78: 630–631

# BOOK REVIEWS

*Fiberoptic Endoscopy and the Difficult Airway*, 2nd Edn. A. OVASSAPIAN. Published by Lippincott-Raven, New York. Pp. 279; indexed; illustrated. Price £103.50.

This book is the second edition of a successful monograph published in 1990 as *Fiberoptic Airway Endoscopy in Anesthesia and Critical Care*. This new edition covers not only fibreoptic tracheal intubation, but also several situations where skilled management of the airway is required. The author points out in the preface that the airway is related to major morbidity and mortality of patients more frequently than is believed and stresses the importance of knowledge and mastering of the skill of airway management. To reflect this view, this edition has been expanded, carefully revised and updated. Five new chapters, including important factors such as safe methods of sedation and the methods for extubating difficult airways, have been added.

In the first of 15 chapters, specifications and functions of the fibreoptic endoscope are described. Sections for cleaning and sterilization are useful: several "do's" and "don'ts" are provided for the use and care of the device. The next two chapters deal with anatomy and pathology of the airway. Several colour photographs of fibreoptic views and more than 40 radiographic images, which are nicely labelled, cover the most relevant pathology. The latter chapter is outstanding.

In chapters four and five, methods of applying topical anaesthesia to the airway and of sedation of patients during fibreoptic procedures are described: in the former, pharmacological features of local anaesthetics, techniques of applications, complications and prevention of complications are discussed. An important concept of the technique—"conscious sedation"—is proposed. In this section, the importance is stressed of providing sedation, analgesia and amnesia, while maintaining communication with the patient, a patent airway and adequate ventilation. Methods to achieve such a state are described succinctly. This is followed by guidelines for non-anaesthetists who might use this technique.

In the subsequent three chapters, techniques are described for fibreoptic tracheal intubation in adults and children and for fibreoptic bronchial intubation. Several drawings and corresponding fibreoptic views allow clear understanding of each procedure.

In chapter nine, several uses of the fibreoptic endoscope in the intensive care unit are shown: evaluation and management of the compromised airway, confirmation of the position of the tracheal tube and exchange of tracheal tubes. Again, drawings and photographs are provided.

The next five chapters focus on difficult airways. The causes, prediction and management of difficult airways are described in a logical sequence. The usefulness of the laryngeal mask and oesophageal airway devices in difficult airway management is highlighted. The book ends with a step-by-step learning method of fibreoptic procedures.

Overall, Professor Ovassapian has achieved his intended goal with great success. This second edition should be useful to specialists of any discipline who engage in airway management. However, non-anaesthetists might find this textbook more useful if the sections for the effects of fibrescopy on haemodynamics or respiratory functions and those for the proper monitoring and management of the patient during the procedure were more comprehensive.

One major difficulty associated with the use of the fibreoptic endoscope is how to learn or teach it. The abundance of clear drawings and photographs in this textbook should enable tutors to teach trainees with considerable ease. We are sure that any person who uses the fibreoptic endoscope will find this book indispensable. Books of this type should be used frequently, rather than just read at libraries, to teach or to acquire the skill. This book is slim enough (279 pages) to carry around and the high quality paper will tolerate extensive use. Every library should ensure that a copy is readily available. All in all, an excellent book.

*Textbook of Anaesthesia*, 3rd Edn. A. R. AIKENHEAD AND G. SMITH (editors). Published by Churchill Livingstone, Edinburgh. Pp. 788; indexed; illustrated. Price £40.00.

What did you read over Christmas? I had the pleasure of browsing through the latest edition of Aitkenhead and Smith. The first edition of this book was published in 1985 and the production of the third edition in 1996 testifies to its popularity. In the past decade Aitkenhead and Smith has become the first choice of many new trainees in anaesthesia. The editors have recruited a considerable number of new authors to ensure a thorough revision of previous contributions. All of the authors have served the editors well, as most chapters are readable, comprehensive and up to date. It is notable that the editors have a major, personal commitment to this book in the form of authorship of nine of the 43 chapters. The majority of authors are associated with the departments in Leicester and Nottingham or perhaps reflect the time spent by the editors working in Scotland. Nevertheless, there are contributions from other anaesthetists; for example Wildsmith, Reilly, Hunter, Fee, Simpson, Willatts and Zideman are well known, authoritative authors

It is easy to find minor aspects of the book to criticize, but deciding on the balance of contents in a book for new trainees must be very difficult. I have doubts about the value of a chapter on the intensive care unit or a short chapter on the management of chronic pain. Some of the topics included in a single chapter do not lie well together. Gynaecological, genitourinary and orthopaedic surgery are strange bed-fellows, but plastic, endocrine and vascular surgery are probably not even on speaking terms.

These quibbles do not detract from an excellent book. Tight editorial control has ensured a coherent style and there is a profusion of figures and tables, a useful list of appendices and a good index. The text is not referenced but a short list of further reading is given at the end of each chapter. The usefulness of this list varies greatly. At a cost of £40 the book represents superb value for money. The reproduction of some figures is less than clear and the binding is unlikely to cope with hard use. However, when the book finally disintegrates, I will happily pay another £40 to replace it.

Both editors have been associated with several other books. I believe that this is their most successful venture; they identified a need and have met that need precisely. The price of this success is that they will soon have to think about the fourth edition.

*G. M. Hall*

*Smith's Anesthesia for Infants and Children*, 6th Edn. E. K. MOTOYAMA AND P. J. DAVIS (editors). Published by Mosby, Chicago. Pp. 999; indexed; illustrated. Price £99.00.

This is the 6th edition of Robert Smith's textbook, first published in 1959. It has long been an established and authoritative multi-authored work. The list of contributors reads as a "who's who" of paediatric anaesthesia in North America.

The growth of knowledge in this area is reflected in the size of the book. This edition is bigger than previous ones and the publishers must have considered using two volumes. Inevitably in a multi-author book, there is a good deal of repetition. Therefore, this is a book for reference rather than an easy read. In general terms I found much of the style dry, and occasionally there is relatively little hard clinical advice to follow up the excellent and thorough science. Many of the illustrations appear rather old and indeed existed in the 1990 edition. This does not give the impression of a "state of the art" book.

The book is divided into four parts: (1) basic principles, (2) general approach to paediatric anaesthesia, (3) clinical management of special surgical problems, and (4) associated problems, including a chapter on malignant hyperthermia and systemic disorders. This latter chapter on systemic disorders is well worth reading, but does not provide a comprehensive reference of the more unusual disorders. There is good advice on asthma and the runny nose. Relatively up-to-date topics (e.g. laryngeal mask, propofol in intensive care and extradurals) are covered but some chapters have few recent references. The chapter on respiratory physiology by Motoyama is hard work, but is a comprehensive review The chapter on pain and an updated chapter on regional anaesthesia are valuable. For bedtime reading, Smith has included a contribution on history. One topic that is consistently covered inadequately in textbooks is the use of ventilators in infants during surgery, and this book is no exception.

However, in general these criticisms are minor, and although there is too much depth for the examination candidate, this is undeniably an excellent reference for all those who encounter children in anaesthetic practice.

*I. Wilson*

*FRCA: Passing the Primary Examination.* H. WILLIAMS, M. HASAN, M. BRUNNER AND N. ROBINSON. Published by Butterworth-Heinemann, Oxford. Pp 150; indexed. Price £14.99.

The examination system of the Royal College of Anaesthetists is designed to assess the worth of anaesthetists to attain specific standards rather than to test if candidates can "jump through hoops". Some areas of this book may suggest that more of the latter occurs that the former. The introduction claims that the book is set to the examination standard, but how this was achieved when compiled before the inception of the new primary examination is unclear.

The book comprises five chapters. The first two cover the examination and the syllabus, information which is available free from the College. Chapter 3 represents 50% of the bulk of the book and is composed of MCQs arranged first in subjects and then in a mixture to mimic an examination paper for practice. Many of the questions look familiar but may provide only false reassurance to candidates for the new primary examination. There is some useful advice on examination technique. Chapter 4 concentrates on the viva exams but comprises only 12% of the book. The style here is somewhat colloquial and some may find it flippant for what is essentially a serious subject for prospective candidates. There is more than one mention of Arsenal football club for example! There are some perhaps misleading assertions, familiar to examiners. Chapter 5, by the authors' admission, is new ground, but they provide a brave attempt at some guidelines and principles in 20 pages.

The introduction to the book states that it is "not just another MCQ book". This is true, but the thirst for such texts by future trainees will ensure that it joins others in that mould.

*D. Fell*

*Difficulties in Tracheal Intubation.* I. P. LATTO AND R. S. VAUGHAN. Published by WB Sanders, London. Pp. 393; indexed; illustrated. Price £40.00.

The first edition of this textbook was an important and relatively unrivalled contribution. It served to focus attention on a subject that had perhaps been taken for granted. Furthermore, it probably inspired many interested parties into making their own contributions. Over the decade since it first appeared, there has been a major explosion of knowledge, and important, interesting differences in approach remain not only across the Atlantic but also between the centres of learning generally. There is also an emerging rivalry with alternative texts. The rapidly expanding knowledge base is not easy to keep up with and difficult to summarize.

While there is a new chapter on intubation for cervical spine injuries it seems unfortunate that there is still no room for major ENT and maxillofacial problems which remain the most technically difficult situations. Some mention of subglottic pathology is at times painfully absent because of an apparent assumption that a tracheostomy or cricothyrotomy will solve airway problems difficult to overcome by other means. There is more space devoted to the difficult airway than before, but it is perhaps unexpected that the problematic airway management for sleep apnoea and related problems, and also the vexed questions on the appropriateness or otherwise of surgical interventions are not included. Understanding of the mechanisms in difficult laryngoscopy has advanced but this receives almost no coverage. One of the continuing problems for studies of predicting difficulty and comparative laryngoscopy has been the failure to standardize methodology and again this might have been referred to when summarizing the current position.

More detail is proposed for the content of teaching programmes for airway management and training for fibreoptic intubations, which is obviously helpful. On the other hand, perhaps what is also required is some advisory knowledge about what should be considered appropriate to attempt and when. In many institutions in the UK it would appear to be the case that for quite difficult elective cases two consultants are often present to cooperate and ensure optimal patient care. It is probably also the case that in practice, diagnosis and appropriate investigative imaging for such elective cases receive more attention than the text generally might imply. There are new large sections to outline the impact of the laryngeal mask airway and the Combitube. Management algorithms for various situations are dealt with sympathetically so as to encourage those who might feel they have a lot to offer compared with others who just want to make sure that they understand the limitations of their abilities so as not to burn bridges. The inclusion of a "legal implications" chapter is an interesting innovation for a UK text and should at least encourage healthy discussion.

Despite the above criticisms this second edition should serve as a focus for further stimulating thought and encouraging research in these important clinical areas. Obviously with rival purchases in a fairly specialist area, anaesthetists need to decide which is the most useful to them. It seems very unlikely that a text of similar size from other UK only authors is imminent.

*P. Charters*

*Patient Safety in Anesthetic Practice.* R. C. MORELL AND J. H. EICHHORN (editors). Published by Churchill Livingstone, New York. Pp. 509; indexed; illustrated. Price £50.00.

This text reviews anaesthesia patient safety endeavours which have occurred within the last 15–16 yr and which are pertinent to current practice. As stated by the editors in the preface, "great efforts have been made to ensure accuracy and to minimize contradictions and redundancy". The multi-author approach is therefore essential in order to provide concise, clearly presented, evidence-based contributions from early workers and leaders in this field.

There are 20 chapters, starting with a brief introduction to the approach to patient safety in the 19th and early 20th centuries. The next four chapters address the need to understand the complexity of anaesthetic and patient monitoring equipment; the one on medical gas vacuum systems used in the USA and therefore subject to different safety regulatory codes, guidelines and standards from those in the UK, is still very informative and the case orientated approach to electrical safety in the following chapter is effective in imparting crucial facts. The chapters on the anaesthetic machine and the advantages and limitations of pulse oximetry and capnography discuss the checks required to ensure the reliability of sophisticated equipment which provide and monitor perioperative care. Misuse or malfunction issues are addressed clearly. The next sections review risk factors in the management of paediatric, adult and pregnant patients; remarkably little is written on the elderly but the impact of anatomical and physiological changes in the pregnant patient is discussed. Information relating to drug safety and patient positioning, together with regional anaesthesia considerations, precede examination of the anaesthetic safety concerns of the recovery unit and particular problems within the intensive care unit, with emphasis on events, safety considerations and standards within these two environments. The case for increasing patient safety through standards and guidelines, practice parameters and algorithms is well argued and supported in further chapters, and the place of the automated anaesthesia record is put into perspective with today's practice.

Overall, this text would be worth buying for the last four chapters alone. These relate to the increasing use of simulators and other training devices in crisis resource management and an authoritative review of the problems known or believed to affect the performance of anaesthetists. The environmental and occupational hazards encountered by anaesthetic personnel are discussed in the penultimate chapter, while the last is an interesting account of adverse events, malpractice claims and the litigation process. The figures and tables are clear and the index logical.

Although written with American practice in mind, this text addresses issues and questions which are relevant to all anaesthetic practitioners in the UK. It is absorbing reading and if not on every anaesthetist's bookshelf it should be found a place in every anaesthetic department where both trainers and trainees can easily access the wealth of commonsense contained within its covers.

## EDITORIAL I

### The expanding role of simulators in risk management

Anaesthetic simulators have been in the news since the 1960s,[1] but the development of theatre-type simulators (TTS)[2 3] in which much of the operating room setting can be reproduced, including the interaction of various personnel, is a feature of only the last decade. Gravenstein[4] has written that the practice of anaesthesia calls for two virtues, compassion towards patients and respect for co-workers, and four abilities, comprehension of facts, grasp of concepts, manual skill and quick response. In several centres in the USA and Canada,[5] in Japan and in continental Europe, there are established simulator training centres in which, to a varying degree, each of these qualities can be developed and tested. The use of simulators can be extended, in some instances, to traumatology, other acute medicine and basic science training.

In the UK the first TTS was inaugurated at Bristol on January 27, 1997. There was extensive media coverage of the event so that public awareness of its possibilities for greater safety has been boosted significantly. The Bristol development, which may soon be followed by others, owes something to an initiative taken by the Council of the Royal College of Anaesthetists, in the early 1990s, who commissioned a report from Professor John Norman and Dr David Wilkins,[6] greatly assisted by several North American colleagues, notably in Gainesville and Boston.

TTS simulators are expensive facilities, some costing in excess of £1m per year. Elements of the total cost include physical accommodation, cost of patient simulator and associated computers and furnishings for the operating room. Accommodation is also needed for screened-off monitoring of events and for induction and debriefing sessions. Human resources include the need for instructors who combine charisma with teaching and, probably, counselling skills. Thespian leanings together with a reasonable command of the complex technology are also important, arguably essential. Not every anaesthetist has all the necessary attributes!

Is the cost justified? Probably no one can give a precise answer because the balance sheet includes not just financial considerations but possible saving of life, and potential for further development of simulation in the future. Simulators may improve and expedite skills training, perhaps especially in countries such as the UK where the anticipated period of training in medical specialties is expected to reduce, and where hospital management pressures for more efficient throughput result in shorter periods of hospital stay with associated reduced clinical access for the trainee.

Simulators could be used for entirely different purposes in relation to the increased public and professional interest in assessing the adequacy of a doctor's clinical performance.[2] Clearly it is important for the specialties to have an agreed, honest and convincing position on this. Whatever happens in the future, to turn away from simulators, or ignore an aspect which obviously some doctors would see as a threat, is not an option.

Some simulator centres include facilities for the display and use of a variety of other training devices, for cardiopulmonary resuscitation, fibre-optic endoscopy and also computer screen-based simulators (SBS). Asbury has pointed out the fact that SBS devices are particularly useful for learning alone or at home because they are obviously relatively mobile.[3] One example which has enjoyed some acclaim in the UK was developed by Byrne, Hilton and Lunn.[7] In this issue of *British Journal of Anaesthesia* there is an interesting account of the use of this device to examine the accuracy of reporting of simulated critical incidents.[8] Eleven anaesthetists in training were individually exposed to a simulated pattern of critical incidents. The purpose was to compare the anaesthetist's written accounts of events after the incidents had been completed with what was presented to them in the first place, and a video tape of their overall performance. The authors of the report were satisfied that the simulation was considered realistic by all participants, and that participants were acceptably experienced to take part. The study suggests that (some) anaesthetists are quite likely to record events according to their perception of the type of complication they believe to be developing. The authors state in their conclusion: "The observed results are more consistent with the recall of patterns or schemata rather than actual events". Such findings may not surprise everyone in the anaesthetic community. Indeed those who remember puzzle sections in childrens' magazines will feel they have always known that patterns of recognition are highly prone to preconception. Within the anaesthetic literature such phenomena have been identified previously.[9 10]

Dr Byrne and Professor Jones are correct in sounding a warning about the analysis of critical incidents and the need for measures to ensure validation of the information that is collected. But there are other important considerations. The reliability of recorded data when more than one doctor is involved in managing a patient and "hand over" strategies are allowed may be poorer than we like to believe. One might also ask if an anaesthetic record which becomes a very central piece of evidence in a court of law is all that some might think. And (craving the Editor's indulgence) do we always read the truth in clinical case reports? These may not be helpful questions, because in the absence of a "black box" recorder there is no obvious answer. Perhaps, of course, simulators can help anaesthetists in their formative years to learn some of the tricks of the mind, and operate in a more disciplined manner.

## EDITORIAL II

# Meningitis after spinal anaesthesia

Bacterial meningitis is a common and devastating illness that presents as a medical emergency requiring considerable diagnostic and therapeutic skills. Mortality is high and even those who recover may suffer a variety of permanent neurological sequelae. Because lumbar puncture (for whatever purpose) bypasses all the natural defence barriers of the central nervous system, it is clear that it carries at least the theoretical risk of introducing infection and causing meningitis. Two routes exist for such infection to reach the CSF. First, failure of aseptic technique could result in the introduction of exogenous organisms into the cerebrospinal fluid. Second, bacteria in the patient's blood at the time of lumbar puncture may gain access to the subarachnoid space because of microscopic bleeding caused by insertion of the needle.

Fortunately, there is good epidemiological evidence that the frequency of meningitis after lumbar puncture is no greater than in the ordinary population. Even in bacteraemic patients the incidence of meningitis after diagnostic lumbar puncture is not significantly different from the expected spontaneous rate.[1] Furthermore, there were no cases of CSF infection in the classic prospective study of 8460 patients undergoing 10 098 spinal anaesthetics performed by Dripps and Vandam.[2] Many of these patients underwent obstetric or urological procedures and were therefore at risk of bacteraemia, the incidence of which has been estimated at 3.6–7.2% after normal delivery.[3] Higher rates might be expected in patients with obstetric complications such as chorioamnionitis or retained placenta, but two retrospective reviews of 27 000 and 505 000 patients who received extradural block in labour revealed only two with infective sequelae.[4 5]

This safety record may be attributed in part to the practice of prescribing antibiotics in such patients to reduce both maternal and neonatal morbidity.[6 7] In an attempt to evaluate this, Carp and Bailey performed a series of studies in which lumbar puncture was performed in bacteraemic rats.[8] Only those animals with a circulating count of *Escherichia coli* (*E. coli*) of greater than 50 colony forming units per millilitre at the time of lumbar puncture developed meningitis. When lumbar puncture was performed in animals without bacteraemia, or in those given a dose of gentamicin, there were no episodes of meningitis. Although *E. coli* rarely causes meningitis the study does support current clinical proposals. Chestnut recommends that spinal or extradural block can be performed in selected infected patients with the proviso that appropriate antibiotic therapy has begun and that the patient has shown a positive response.[9] An antibiotic with a broad spectrum of activity seems advisable given the suggestion that meningitis after recent spinal anaesthesia is often caused by unusual or nosocomial infection.[10] Such therapy might serve only to delay the onset of symptoms, but when meningitis occurs 25 days after a spinal anaesthetic (for a haemorrhoidectomy) it does seem more likely that it is coincidental.[11]

Antibiotic therapy is usually introduced very early in any patient with meningeal symptoms, particularly if there are other signs of infection or a potential "aetiological factor" such as lumbar puncture for spinal anaesthesia. When purulent CSF is obtained from such patients, but no organisms are grown on culture, there is often an assumption that the antibiotic has inhibited bacterial growth. However, it is important to remember that bacteria are not the only cause of meningitis. The viral condition is generally much more benign, but may be caused by a wide range of organisms, and Coxsackie B infection has been described after extradural block on at least one occasion.[12] Genital HSV infection occurs in 0.5–1% of pregnant women and HSV meningitis has been reported in 8% of those with the primary infection.[13] It is a matter of mere epidemiological coincidence that some patients who have received spinal or extradural block could develop this infection.

However, most cases of meningitis after central nerve block are probably aseptic in origin. Fifty years ago aseptic meningitis was not an uncommon complication of spinal anaesthesia and by 1947 more than 100 cases had been described in the literature and an incidence of 0.26% was quoted in a summary report of approximately 46 000 spinal anaesthetics.[14 15] However, the incidence declined dramatically during the 1950s after a series of studies that had implicated chemical contamination of the CSF as the cause. It was shown in 1937 that this could result in meningeal irritation and animal studies showed that a whole range of detergents and chemicals could produce symptoms and histological changes consistent with aseptic meningitis.[16–18] Recognition of these factors led to improvements in technique and equipment and these have reduced markedly the incidence of problems, although sporadic case reports still emphasize the need for attention to detail.[19–21]

Another important, but much less widely appreciated, cause of aseptic meningitis is systemic drug administration. Drug-induced meningitis has been reported after non-steroidal anti-inflammatory agents, antimicrobials, ranitidine, carbamazepine and azothiaprine. In 1992, Marinac summarized 31 cases after ibuprofen alone in a literature review.[22] The syndrome is more common in females with underlying autoimmune or collagen vascular disorders, but is occasionally reported in normal individuals, and is presumed to be an acute hypersensitivity reaction. There are some immunological data to support this hypothesis.[23 24] Signs and symptoms typically appear a few hours after drug ingestion, but may be delayed by weeks. In addition to the usual features of meningitis there may be periorbital oedema, conjunctivitis, hypotension, parotitis, pancreatitis, lethargy, diplopia, seizures and confusion. Fever is common. The CSF picture varies greatly, but there is generally polymorphonuclear pleocytosis, increase in protein concentration and normal glucose. Symptoms worsen with continued drug administration, but most patients recover fully in a few days after the offending medication is stopped. Definitive diagnosis requires re-administration of the drug to the patient.

Irritation and inflammation of the meninges must be accepted as a potential complication of spinal anaesthesia. Perhaps the greatest advantage of the technique is that only a tiny dose of drug is required to produce a major degree of block, the main reason being that all the barriers surrounding the spinal cord and nerve roots are bypassed by the injection and the drug reaches its site of action easily. However, all the natural protection of the CSF is circumvented also. As long as equipment and drug solutions manufactured to modern standards are applied with a sound aseptic technique, the incidence of complications should be very low and the occasional case of meningitis is likely to be coincidental. However, every case should prompt a thorough consideration of all possible aetiological factors and this must include the equipment and technique used. When there is no obvious bacterial infection the possibilities of viral infection, chemical contamination and drug-induced meningitis must each be investigated. The latter is particularly important given that two groups of drugs used widely in anaesthesia (NSAID and $H_2$ blocking agents) have been shown to cause the condition. We have traced five cases of meningitis after dural puncture in the recent medical literature[19–21 25 26]; four of these were aseptic in nature but no intercurrent drug history was given and the possibility of drug-induced meningitis was not raised.

CLINICAL INVESTIGATIONS

# Inaccurate reporting of simulated critical anaesthetic incidents

A. J. BYRNE AND J. G. JONES

## Summary

Eleven anaesthetists completed a simulated anaesthetic which was deliberately complicated by a slow progressive bradycardia followed by an episode of severe bronchospasm. After the simulation, each anaesthetist was asked to complete an anaesthetic chart and a critical incident report. Considerable discrepancies were found between the anaesthetists' written accounts, a videotape of their performance and actual data from the simulator. During the simulations, all of the anaesthetists reacted appropriately and treated their "patient" successfully but their written accounts showed a tendency to record "typical" rather than actual events and to ignore events not consistent with their final diagnosis. Only four anaesthetists mentioned bradycardia in their written description and none accurately described the changes in arterial pressure during the episode of bronchospasm. The findings are in keeping with other studies which suggest that people record events as "schemata" rather than as collections of discrete facts. These results have significant implications for those involved in the teaching of anaesthesia and in the analysis of critical incidents. (*Br. J. Anaesth.* 1997; **78**: 637–641).

**Key words**
Anaesthesia, audit. Computers, simulation Model, computer simulation. Anaesthetist, training.

The Anaesthetic Computer Controlled Emergency Situation Simulator (ACCESS)[1] has been used over the past 3 yr to provide basic training for junior anaesthetists and to assess their ability to deal with critical incidents. The simulator consists of a resuscitation manikin in place of a patient, an anaesthetic machine/ventilator and computer simulated monitors. The anaesthetic machine is a basic "Boyles machine" complete with TEC3 vaporizer, which appears to function normally, but which has been modified to avoid the use of real volatile agents or nitrous oxide. A Manley MP3 ventilator was used during this study. The monitors provide information on non-invasive arterial pressure, pulse oximetry, ECG, inspired oxygen concentration and end-tidal carbon dioxide concentration. Simulations are presented as clinical scenarios which test the ability of the trainee to deal with a specific emergency. The simulations are realistic, as judged by those who have taken part,[1] and require appropriate manual responses to be performed by the trainee, for example, hand ventilating the lungs of the "patient" or injecting drugs.

During previous training sessions it was noticed that trainees often seemed to have misinterpreted the data presented and, when asked to describe their actions, their descriptions often contained factual inaccuracies. However, these inaccuracies were usually plausible and consistent with their stated final diagnosis. For example, if they failed to notice a gradual bradycardia, they often stated that heart rate had been normal initially and had then changed suddenly.

This study was designed to test if the observed anomalies arose from the anaesthetist misunderstanding the simulation, from the anaesthetist's inability to manage the simulated critical incident, or if the problem lay in the ability of the anaesthetist to remember events accurately.

## Methods

Eleven trainee anaesthetists, with 3–8 yr clinical experience, volunteered to take part in a single simulation, with no opportunity for trial runs or practice. None had used ACCESS previously and they were told only that their performance would be evaluated during a standard simulated anaesthetic. The same investigator gave each anaesthetist a verbal introduction to the simulator lasting 3–4 min.

During each simulation, the investigator acted as a helpful aide, to provide physical assistance for any task, but not to provide useful diagnostic or therapeutic information. However, the investigator did answer questions related to the simulation, for example, if cyanosis was present or if the breath sounds had altered in character.

Each anaesthetist was introduced to the simulation as if taking over a routine anaesthetic from a colleague. They were shown a preoperative assessment form and were told about the anaesthetic technique being used. The "patient" for each anaesthetist was based on a real case and was young and healthy. The "operation" was an open reduction and internal fixation of an ankle fracture, the patient having had a local anaesthetic ankle block and been

Correspondence to A. J. B.

paralysed, the trachea intubated and the lungs ventilated 20 min before the anaesthetist taking over the case. Drugs "used" were thiopentone, vecuronium, fentanyl and bupivacaine. Each anaesthetist was allowed to ask questions and to check the settings on the ventilator, anaesthetic machine and monitors.

The simulation was started as soon as the anaesthetist was familiar with the situation and ended when the "patient" had been treated correctly and was stable. Each entire episode was videotaped for later analysis. At the end of each simulation, each anaesthetist was asked to immediately complete an anaesthetic chart and a critical incident report, covering the period of simulation. They were not asked questions about any specific event, but were simply asked to record the simulated events in free text, as if it were a real case. The computer printed out a timed list of all significant events and the heart rate of the "patient" during the period of each simulation. This printed output was not made available to the anaesthetist.

Each simulation contained two critical incidents: phase one, a bradycardia and phase two, an episode of bronchospasm induced by a dose of antibiotic. During phase one, heart rate started at 80 beat min$^{-1}$ and decreased in a linear manner, by 10 beat min$^{-1}$ every 3 min, with only minor random variation. There was no consistent change in arterial pressure. It was expected that at some point the anaesthetist would administer a dose of anticholinergic drug to correct the bradycardia. When this dose had been given and bradycardia corrected, the simulation moved into phase two. The purpose of the first phase was to compare the actual change in heart rate (from the simulator printout) with the change documented on the anaesthetic chart and the anaesthetist's perception of events from their written account.

At the start of the second phase, the anaesthetist was told that the surgeon had requested that a dose of i.v. flucloxacillin be given. As soon as the anaesthetist administered some of the flucloxacillin, airways resistance increased markedly, simulating an episode of bronchospasm. This was manifest by the Manley ventilator being unable to deliver the set tidal volume. Arterial pressure remained normal for two further readings (at least 2 min) and then rapidly became unrecordable. This simulated a reduced cardiac output secondary to air trapping and was based on a real critical incident. It was expected that the anaesthetists would administer i.v. fluids and adrenaline, although any reasonable combinations of treatment would have resulted in the "recovery" of the "patient". For example treatment with salbutamol, aminophylline or adrenaline, in appropriate doses, would all result in a reduction in airways resistance. When these treatments had been given and the "patient" had stabilized, it was planned that the simulation would be terminated. The purpose of this phase was to observe if the anaesthetists would be aware of the changes in arterial pressure, if these changes would influence diagnosis/treatment and if the information would be recorded in their written account.

The realism of the simulations was assessed by asking the anaesthetists to answer two questions, using a linear analogue score from 1 (unrealistic) to 10 (realistic), in response to the questions "How do you rate the realism of the simulation?" and "How do you rate the realism of your responses to the simulation?". This assessment was performed to ensure that ACCESS was providing a level of realism.

## Results

All anaesthetists responded appropriately to the simulation; all "patients" were treated appropriately and all simulations were continued to a successful conclusion.

### RESPONSES TO SIMULATED BRADYCARDIA

In the first phase, all 11 anaesthetists diagnosed bradycardia and administered an adequate dose of anticholinergic, either atropine 300–600 μg or glycopyrronium 200–400 μg. However, three anaesthetists failed to document bradycardia and two failed to record administration of a drug on their anaesthetic chart.

In the critical incident report, only four of the 11 anaesthetists mentioned bradycardia, and these comments are reproduced in table 1. Only the first anaesthetist described the simulation accurately, with the next two anaesthetists being less specific. Anaesthetist No. 4 described the actual, gradual onset of bradycardia as a single rapid episode, with associated hypotension (which was not present). Anaesthetist No. 5 ignored the bradycardia and described an episode of hypotension. (Actual systolic arterial pressure values shown, at minute intervals, were: 102, 90, 88, 96, 98, 115, 101, 92, 100, 104 and 110 mm Hg.)

Subsequent inspection of the anaesthetic charts confirmed that all 11 anaesthetists were unable to

| | |
|---|---|
| Expected | There was a gradual decline in heart rate from 80 to 35 beat min$^{-1}$ over the first 15 min, otherwise the patient was stable. |
| Anaesthetist (No.) | Reported events |
| (1) | "... gradual decline in HR noted No change in ECG. No change in BP. No cause evident." |
| (2) | "One episode of bradycardia during GA, responded to atropine (300 μg) otherwise CVS +$O_2$ Sats >96%." |
| (3) | "Approximately 40 min into the procedure, which was otherwise unremarkable other than bradycardia (sinus) to 42 beat min$^{-1}$. $R_X$ atropine." |
| (4) | "The first 30 min of anaesthesia and surgery was stable. The "patient" then developed a bradycardia, with the heart rate decreasing to about 30 beat min$^{-1}$. Arterial blood pressure was reduced but still maintained within acceptable limits." |
| (5) | "Initially everything was fine, then BP started to slowly drop from 120 to 90 systolic. Responded to Hartmann's 1L." |
| (6–11) | No comment made about bradycardia |

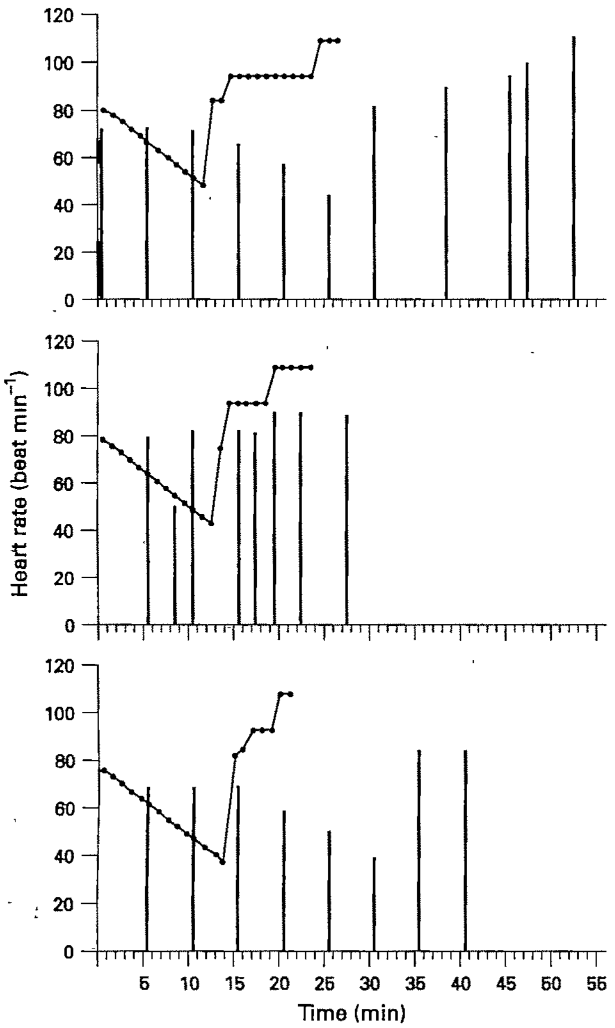

*Figure 1* Actual and recorded heart rates for anaesthetists Nos 9, 10 and 11.

record accurately the simulated events or their time scale. Figure 1 shows examples of actual heart rates plotted on the same scale as those recorded by the anaesthetist. Overall, subjects tended to record an initial stable period, followed by a brief bradycardia, rather than a gradually evolving bradycardia. The anaesthetists' charts often showed a time scale twice as long as the real events.

RESPONSES TO SIMULATED BRONCHOSPASM

All 11 anaesthetists described the second phase of the simulation, but there were significant differences between actual and recorded events.

*Table 2* Expected and observed descriptions of phase two of the simulation by anaesthetists

| Expected | After a test dose of flucloxacillin, patient developed bronchospasm. Arterial pressure was initially normal but decreased rapidly after 2 min. Patient responded to i.v. and adrenaline. |
|---|---|
| Anaesthetist | Reported events |
| (1) | "following i.v. fluclox, *P*aw increased such that the Manley was ineffective. A diagnosis of anaphylaxis was made, $Fi_{O_2}$ to 100%. IPPV by bag. Auscultation, widespread wheeze bilat. Adrenaline 100 µg given i.v with quick result. As compliance improved => Manley. 1% ISO throughout. No desaturation. No hypotension." |
| (2) | "On administering flucloxacillin 50 mg during CVS collapse, airway (*P*) increased + Sats decreased to 91%." |
| (3) | "I was then asked to administer flucloxacillin which I did i.v. Over the course of the next few minutes, the 'patient' dropped his $Sa_{O_2}$% to 92–93%, developed bilateral bronchospasm, and also progressively dropped his blood pressure." |
| (4) | "'patient' developed bronchospasm + hypotension in response to i.v. flucloxacillin " |
| (5) | "Asked to give antibiotic. No Hx of allergy. Diluted flucloxacillin 1 g in 10 ml. 2 ml test dose—bronchospasm, hypotension." |
| (6) | "Immediately after flucloxacillin solution 1 ml—tight bronchospasm with ventilator unable to deliver volume ... Minimum $Sa_{O_2}$ 92%, $ETCO_2$ to 3.3 kPa. BP always strongly palpable—minimum recorded 89/56 (although BP machine malfunctioned for 2 min during event)" |
| (7) | "Flucloxacillin 1 g i.v. Events: (chronologically) (1) bronchospasm, (2) no BP recorded, (3) back to normality" |
| (8) | "After giving test dose of fluclox. 'patient' became difficult to ventilate and was wheezy with very little air entry suggesting severe bronchospasm." |
| (9) | "Test dose of 50 µg given. 'Patient' developed bronchospam evident by increased *P*aw and decreased AE within 30 s. No response to salbutamol via ETT. Subsequent hypotension (no BP on Dinamap) but faint carotid pulse." |
| (10) | "1-ml test dose given > bronchospasm > hard to ventilate with halothane, i.v. salbutamol + adrenaline + fluids." |
| (11) | "Bronchospasm + 'anaphylactic' hypotension 2° to i.v. fluclox ... Min BP 52/mm $Sp_{O_2}$ 92%" |

*Table 3* Assessment of realism by anaesthetists, using visual analogue scale (0=unrealistic, 10=realistic)

| | Median score | Range |
|---|---|---|
| How do you rate the realism of the simulations? | 8 | (6–8) |
| How do you rate the realism of your responses to the simulation? | 7 | (5–8) |

In their critical incident reports (table 2), none of the anaesthetists commented that arterial pressure had been normal for 2 min after bronchospasm had started. Only two anaesthetists (Nos 7 and 9) correctly described the actual sequence of events. Analysis of the videotapes however, showed that most of the anaesthetists had looked at the arterial pressure reading soon after bronchospasm had started. Seven of the 11 anaesthetists either stated that arterial pressure was normal and/or increased the inspired concentration of volatile agent, indicating that most were aware of the initially normal arterial pressure. For example, anaesthetist No. 2 stated "Sats OK, BP OK" just before starting to treat the bronchospasm with aminophylline. Yet the same anaesthetist described, in the written account, the hypotension ("CVS collapse") as occurring before or at least at the same time as the bronchospasm.

The answers to the questionnaire (table 3) showed that the anaesthetists thought that the simulations were realistic.

## Discussion

This study has shown that a group of trainee anaesthetists treated a simulated "patient" in a realistic manner. However, their written accounts of events were influenced heavily by their own final diagnosis, with events being altered or omitted to fit with this diagnosis.

### SIMULATED BRADYCARDIA

The results from phase 1 showed a tendency for the anaesthetists to ignore any events which they perceived as not being directly related to their "main" problem, in that seven of 11 did not report that bradycardia had occurred. They also showed a tendency to "normalize" events. A gradual decrease in heart rate is unusual, but this was mentioned by only one anaesthetist who wrote, "No cause evident". Anaesthetists Nos 2, 3 and 4 mentioned that bradycardia had occurred. The implication is that the anaesthetists were not able to remember individual values for each of the variables shown, but were recording events as complete episodes. This view is reinforced by the recorded values on the anaesthetic charts (fig. 1) which tended to show an initial period of normal heart rate followed by sudden bradycardia. In other words, the first phase of the simulation had been remembered as two discrete episodes, an initial episode of normality, followed by an episode of bradycardia. When writing about the events afterwards, values for heart rate and arterial pressure were obtained from their own mental models of those events.

This may also explain why anaesthetist No. 5 reported a single reading of systolic arterial pressure of 88 mm Hg as an episode of hypotension. This was only a small decrease from the real initial value of 102 mm Hg. However, he reported an initial value of 120 mm Hg, that is a "normal" arterial pressure, which would make a subsequent systolic pressure of 88 mm Hg more significant. The next reading of a systolic arterial pressure of 115 mm Hg may have indicated that the i.v. fluid had been successful in treating the "hypotension", reinforcing the diagnosis. A later value of 90 mm Hg was then ignored.

### SIMULATED BRONCHOSPASM

During phase 2 all anaesthetists responded appropriately to the increased airways resistance and appeared to be aware of the normal arterial pressure initially and to make a diagnosis of isolated bronchospasm. Subsequently, when arterial pressure began to decrease, the anaesthetists seemed to change the diagnosis from bronchospasm to a generalized anaphylactic reaction. Then, when their treatment began to be effective and heart rate and arterial pressure began to return to normal, the new diagnosis of anaphylaxis with cardiovascular collapse was reinforced. Therefore, the episode was remembered as an episode of anaphylaxis and any inconsistent information was subconsciously suppressed, or not remembered.

Within the specialty of anaesthesia, an accurate record is of prime importance and errors have tended previously to be described in terms of inattention or misdiagnosis. This study tested anaesthetists during daylight hours, without the distractions of bleeps, telephone calls and audit forms. The short period of the study also implied that boredom was unlikely to have been a factor. All "patients" were treated correctly and the anaesthetists appeared to have few difficulties in understanding the data presented by the simulator. Although an anaesthetist "taking over" a case half way through may not be regarded as "best practice", trainee anaesthetists are often asked to take over the care of patients for short periods. This is usually regarded as acceptable provided the incoming anaesthetist is briefed correctly, as was the case in this study. The conclusion is therefore that the errors observed were caused by problems with the recall of events by the anaesthetists.

The problems described here have been observed in other fields such as aviation and the nuclear power industry and have been the subject of considerable research.[2 3] In particular, our limited capacity to retain numerous discrete elements of data[4] and the tendency of subjects to act on the present value of a variable rather than the trend[5] have been demonstrated. The observation that memories are stored as typical "patterns" or "schemata" has been described as far back as 1934.[6] The relevance to anaesthetic practice was described by Allnutt in 1987, "Thus, with the highest integrity, we soon start reporting not what happened, but *what must have happened*" (authors italics).[7]

These problems have several important consequences for those analysing critical incidents. First, if anaesthetists are taught to deal with a list of well defined emergencies, with their attendant signs, symptoms and solutions, it is likely that they may try subconsciously to make any real emergency "fit" one of this list. Any record of the event may then resemble the textbook example more than the real events, with the consequence that vital details may be obscured. In particular, complications or associations which have not been recognized previously may continue or go unreported. Second, any aspect of the real event which was unusual or incompatible with the diagnosis made tends to be ignored or reduced in value. Any details recorded tend to support the final diagnosis.

This study can be criticized for not using real cases and for the analysed records not having been made contemporaneously. However, the anaesthetists reacted appropriately to the simulations and rated the experience as realistic. This is reinforced by the observation that one anaesthetist administered a dose of neuromuscular blocker to stop a plastic resuscitation manikin from "coughing". Although the records were made immediately after the event and not at the same time, it is unlikely that during a real critical incident anaesthetists would have the time to fill in an anaesthetic chart or to review trends on a monitor. Therefore, during a critical incident, when decisions have to be made, anaesthetists have to rely on their own memory for details of recent events, and that is what has been tested here.

Finally, our knowledge of anaesthetic emergencies, their diagnosis and treatment has largely been built up from analysis of critical incident forms. This study indicates that the information derived from that source may not reflect actual events. Although some anaesthetic machines are capable of providing detailed case records, monitors may not provide accurate readings during a sudden catastrophic event such as anaphylaxis. In addition, they do not record all the actions of the anaesthetist. Cases where the automated record differed substantially from the events perceived by the anaesthetist may cause difficulties for both trainers and those seeking to defend against litigation. Automated recording of monitoring and videotaping of the anaesthetic would seem to provide the best solution, but this is unlikely to receive widespread acceptance and has significant cost implications. Overall, the most immediate solution is for those involved with the analysis of critical incidents and in the debriefing of the participants to be aware that written and verbal accounts of events may be inaccurate. In addition, trainers need to ensure that anaesthetists are aware of the limitations of their perception. In particular, it is vital for anaesthetists to constantly re-check diagnoses and assumptions as a critical event develops.

# Propofol and bradycardia: causation, frequency and severity

M. R. TRAMÈR, R. A. MOORE AND H. J. MCQUAY

## Summary

As part of the development of a model for the study of adverse events, we have investigated the risk of bradycardia with propofol. A systematic search for any type of report, published and unpublished, was made to review the evidence that propofol increases the risk of bradycardia, asystole and death from bradycardic events. Quantitative and qualitative analyses of data with different strengths of evidence were performed. Sixty-five published and 187 spontaneous reports to drug monitoring centres described with different strength of evidence a biological basis for propofol-induced bradycardia, 1444 bradycardias, 86 asystoles and 24 deaths. In controlled clinical trials, propofol significantly increased the risk of bradycardia compared with other anaesthetics (number-needed-to-harm 11.3 (95% confidence interval 7.7–21)). In paediatric strabismus surgery the number-needed-to-harm was 4.1 (3–6.7). One of 660 patients undergoing propofol anaesthesia had an asystole. The risk of bradycardia-related death during propofol anaesthesia was estimated to be 1.4 in 100 000. Data from the phase IV study of propofol did not agree with data from controlled studies. Propofol carries a finite risk for bradycardia with potential for major harm. Study of adverse events should be made with systematically searched data and, in contrast with study of efficacy, not restricted to randomized, controlled trials. (*Br. J. Anaesth.* 1997; **78**: 642–651).

**Key words**
Anaesthetics i.v., propofol. Heart, heart rate. Complications, bradycardia. Complications, asystole. Anaesthesia, audit.

Propofol has been available since the early 1980s. It has gained widespread popularity because it is thought to have specific advantages compared with other anaesthetics, such as favourable kinetics,[1] smooth induction characteristics, a recovery profile with a low incidence of adverse effects[2] and non-hypnotic therapeutic properties.[3] It was suggested that the excellent haemodynamic state was of particular use in paediatric patients.[4]

During propofol anaesthesia a low heart rate may occur despite decreased arterial pressure.[5 6] Absence of reflex tachycardia may be considered beneficial because it is not associated with an increase in myocardial oxygen consumption. However, observational reports on profound bradycardia and asystole with the use of propofol in healthy adult patients, despite prophylactic anticholinergics, have been published repeatedly.[7–9] Severe, refractory and fatal bradycardias in children in the ICU have been observed with long-term propofol sedation.[10–12] The question has been raised of when, if ever, case reports become good enough evidence on which to base practice.[13]

There is now strong evidence from a meta-analysis of all relevant randomized controlled trials (RCT) that propofol anaesthesia, compared with other anaesthetics, increases substantially the incidence of the oculocardiac reflex (OCR) in paediatric strabismus surgery despite the use of prophylactic anticholinergics.[14] The OCR, a trigemino-vagal reflex, may induce severe bradycardia and asystole. Fatal outcome has been described.[15 16]

These data from both observational reports and RCT suggest with different strengths of evidence, and hence different powers of causation and estimation of frequency, a clinically relevant relationship between propofol and bradycardia or asystole.

## Methods

A systematic search was made for any type of report (any or no study architecture) of bradycardic events during propofol anaesthesia. MEDLINE (KnowledgeServer) was searched (1984 to December 95), not restricted to the English language, with the terms *propofol, adverse effects* (sub-heading), *bradycardia, asystole* and *death,* and combinations of these words. Reference lists from published reports and review articles on propofol, and the authors' in-house bibliography on propofol were hand searched. Thirty-eight national centres participating in the WHO drug monitoring scheme were contacted by letter and asked for detailed information on spontaneous reports (yellow card scheme) on propofol and bradycardic events. The manufacturer of propofol was contacted to provide relevant data. Abstracts from scientific meetings, reports of propofol sedation in the ICU, reports of death not definitely related to bradycardic events (cardiovascular collapse without obvious relationship to bradycardia

Correspondence to M. T.

or asystole, for instance[17]) or of arrhythmias other than bradycardia[18] were not considered.

All types of reports were sought which supported a biological basis for propofol-induced bradycardia, reported absence or presence of bradycardic events with propofol anaesthesia or studied additional information on propofol-related bradycardia (prevention, therapy, risk factors, dose–response, pharmacological interactions).

Based on observational reports[9 19] there was a prior hypothesis that there is a potential continuum with propofol-induced bradycardia. This implies that bradycardia, which is usually perceived as minor harm, is actually potential major harm because of the possibility of its progressing to actual major harm, asystole and possibly to a disaster. Therefore, lowering of heart rate, OCR, and first or second degree AV blocks, as defined in the original reports, were considered as potential major harm. Asystole, cardiac arrest, absence of QRS complexes, electromechanical dissociation, and III degree AV block, as described in the original reports, were classified as major harm. Death after any bradycardic event was classified as disaster. Need for treatment (anticholinergics, catecholamines, external chest massage), concomitant symptoms (convulsion, for instance), and spontaneous resolution, duration, recurrence or grading of events (severe bradycardia, for instance) did not alter this classification.

Information on type of reports, patient characteristics, surgery, propofol regimen, concomitant drugs, anaesthetics in controls, definition, number and treatment of bradycardic events, and outcome was taken from each report. Dichotomous data on bradycardic complications in propofol and control groups were extracted from controlled trials.

The L'Abbé plot[20] of bradycardic event rates with propofol compared with bradycardic event rates with controls was used as a graphical means of exploring the risk of propofol and the homogeneity of the data set. A scatter predominantly lying between the line of equality and the propofol axis suggested an increased risk with propofol and homogeneity. Odds ratio (OR) estimates were calculated with 95% confidence intervals (CI) using a fixed effect model.[21] If any cell of a sample was zero, then 0.5 was added to all cell sizes for that sample.[22] A lower limit of the 95% CI of the OR $>1$ indicated a statistically significant increased risk with propofol. Number-needed-to-harm (NNH) and 95% CI were calculated in the same way as number-needed-to-treat.[23 24] Odds ratio and NNH were calculated separately for individual reports and by combining single propofol or control arms. It was assumed that propofol without nitrous oxide had the same risk of bradycardia as propofol with nitrous oxide; these arms were combined for analysis. The "rule of three"[25] was used in large series to estimate the implication of zero numerators. Calculations were performed using Excel v 5.0 on a Power Macintosh 7100/66.

## Results

Sixty-five published reports (1985–1995) were considered. Types of reports were randomized, controlled trials, controlled trials without randomization, a review of clinical studies, several case series and published case reports. Additional unpublished data came from 12 drug monitoring centres. Information from the manufacturer of propofol did not add to these data. No cohort or case-control study was found.

### BIOLOGICAL BASIS

Uncontrolled experiments in dogs with pharmacological autonomic denervation led to the conclusion that propofol may have a direct effect on sinus activity.[26] In an RCT in dogs, propofol decreased arterial pressure but failed to induce reflex tachycardia.[27] However, in rabbits[28] propofol increased heart rate, and in sheep[29] both heart rate and arterial pressure were increased with propofol. These findings were considered to be unexpected, contrasting with the response in human[28] and eventually were considered species-specific.[29]

Haemodynamic effects of propofol induction and maintenance were tested in several small clinical series[5 6 30–32] and one RCT.[33] Heart rate was stable or even decreased despite a significant decrease in arterial pressure.[6 30 33] Both baroreflex resetting[5 31] and a particular autonomic milieu predisposing to a parasympathetic response to noxious stimulation during propofol anaesthesia[32] were suggested as principal mechanisms of this relative bradycardia.

### BRADYCARDIC EVENTS WITH PROPOFOL IN CONTROLLED TRIALS

Seventeen relevant controlled trials were randomized.[34–50] In two further trials no method of randomization was mentioned.[51 52] Data from these 19 controlled clinical trials were pooled for analysis. In more than 1200 patients, propofol was compared with other regimens for induction or maintenance of anaesthesia, or both, and bradycardic events were reported as dichotomous outcomes (table 1). Children and adults, mainly ASA I or II, were studied in a variety of surgical settings. In five of 11 paediatric RCT the lower age limit was 6 months to 2 yr,[40 48 50 53 54] and in another three, age limits were not mentioned.[44 47 55] In one RCT,[37] five patients had heart disease and were classified as ASA III. Prophylactic anticholinergics were given in 11 studies. The event rate scatter suggested an increased risk of bradycardia with propofol and a homogeneous pattern in these trials (fig. 1). Across all controlled trials the risk with propofol, compared with other anaesthetics, was significantly increased; the combined NNH for one bradycardic episode was approximately 7 (table 1).

In an RCT a bradycardia ended in an asystole in a young woman undergoing a minor gynaecological procedure with propofol.[36] The patient was resuscitated successfully after external chest massage for 30 s and i.v. atropine. Her postoperative electrocardiogram showed a pre-excitation syndrome. The NNH point estimate for an asystole with propofol compared with another anaesthetic across all controlled studies was 660 (table 1).

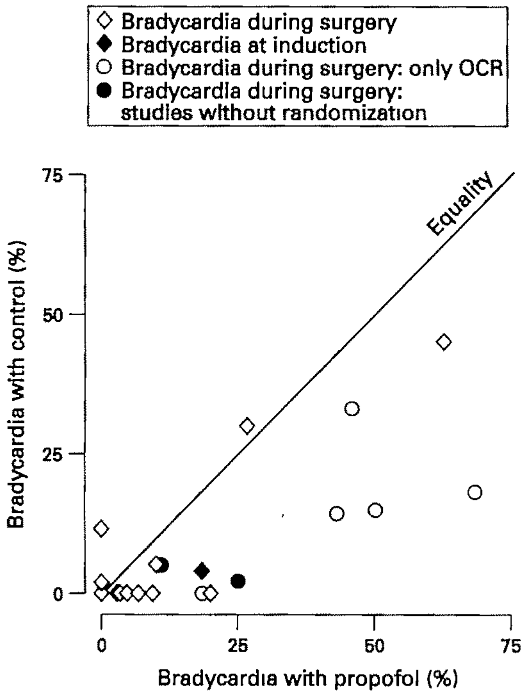

*Figure 1* Propofol and bradycardic events. Each symbol represents one study. Numbers indicate percentages of patients with a bradycardic event with propofol or a non-propofol anaesthetic (control). Data from 17 randomized, controlled trials and two controlled trials without randomization.

In five RCT with more than 330 children undergoing strabismus surgery the average incidence of an OCR in controls was 16.2%.[39 40 44 48 50] In these studies the combined NNH for an OCR with propofol was 4, despite prophylactic anticholinergics (table 1). In all other controlled trials (12 RCT and two controlled trials without randomization) the average incidence for bradycardia in controls was 6.4%, and the NNH to produce a bradycardia with propofol was approximately 11 (table 1).

## BRADYCARDIC EVENTS WITH PROPOFOL IN CASE SERIES

In a small series, one of 30 patients needed atropine to treat bradycardia.[56] An early review of the safety and tolerance of propofol based on 27 separate studies with 1459 patients receiving propofol reported one cardiac arrest.[57] A cardiac conduction defect was thought to be a contributory factor to this major complication.[57] No bradycardic events were reported in a post-launch trial involving 879 patients receiving propofol.[58] In more than 2600 children and adults undergoing a standard propofol anaesthetic, two III degree AV blocks and one bradycardia progressing into an asystole were described in three healthy adults.[59]

The results of a propofol phase IV study were described in two separate analyses.[60 61] One analysis concentrated on any type of adverse event during propofol anaesthesia, as reported by anaesthetists and nurses.[60] Without definitions, this article documented intraoperative bradycardia in 102 (0.4%), severe bradycardia in four and cardiac arrest in two of 25 981 patients, respectively.[60] The second analysis of the same data concentrated specifically on the haemodynamic effects of propofol anaesthesia and reported a 2% incidence of bradycardia (heart rate lower than 50 beat $\text{min}^{-1}$) at induction and an additional 2.8% during maintenance.[61] In a *post hoc* analysis, bradycardia was significantly associated with beta-blockers, but not with anticholinergics, opioids, neuromuscular blocking agents or heart disease.[61] Hug and colleagues concluded that even in the hands of inexperienced anaesthetists propofol had a low incidence of untoward haemodynamic changes and that these changes were predictable.[61]

## BRADYCARDIC EVENTS WITH PROPOFOL IN PUBLISHED CASE REPORTS

Seventeen published case reports from 10 countries described, in 25 adults, 13 bradycardias, three heart blocks, 13 asystoles, one electromechanical dissociation and one death.[7–9 19 62–74] Seven bradycardias progressed to asystole. In an elderly patient with atrial flutter, electromechanical dissociation without preceding bradycardia had a fatal outcome; post-mortem examination excluded acute myocardial ischaemia.[74] Case reports were published between 1987 and 1994 without any chronological clustering.

## BRADYCARDIC EVENTS WITH PROPOFOL IN SPONTANEOUS REPORTS TO DRUG MONITORING CENTRES

Twelve of 38 national drug monitoring centres responded to our inquiry. In three countries (Croatia, New Zealand, Thailand) no bradycardic events were reported. The other nine countries reported 95 bradycardias, 65 asystoles and 23 bradycardia-related deaths during propofol anaesthesia: Australia (six reports), Belgium (six), Canada (four), Denmark (five), Eire (11), Norway (five), Sweden (two), Switzerland (one) and UK (147). Twenty-five bradycardias progressed to asystole; nine of these were fatal. Death was documented in another 14 patients after asystole.

## ADDITIONAL DATA

In RCT in children, the reduction in heart rate with propofol was more pronounced when alfentanil was also given,[55] was not dose-dependent[54 75] and was more pronounced in children less than 2 yr of age than in older children[53] but was not different between the ages of 3 and 15 yr.[75] One study without randomization reported a lower incidence of OCR with a higher propofol dosage regimen.[76]

In adults, anticholinergic agents prevented propofol-induced bradycardia but not hypotension.[77–79] Established bradycardia was unresponsive to increasing doses of i.v. atropine.[80] Bradycardia was potentiated by fentanyl,[81 82] but was not increased when lignocaine was given to prevent propofol pain at injection.[83] A tendency to slower heart rates was seen in older patients (65–80 yr) undergoing propofol anaesthesia compared with younger patients (25–40 yr).[84] A dose–response was seen for hypotension but not for bradycardia in elderly patients.[85]

## ESTIMATION: ABSOLUTE RISK OF BRADYCARDIC EVENTS WITH PROPOFOL

The likelihood of bradycardic events with propofol depended on the type of report (table 2). In 19 controlled trials the average incidence of bradycardia with propofol was 23.3% in 660 patients (15.2% when OCR was excluded). In case series the incidence of bradycardia with propofol was 4.8% (1179 bradycardic events in 24 578 patients).

In controlled trials one of 660 propofol patients developed an asystole, corresponding to an incidence of 15 asystoles in 10 000 patients (table 2). In uncontrolled series, six asystoles were described in 30 936 patients receiving propofol, corresponding to an incidence of 1.9 asystoles in 10 000 treated patients (8.1 in 10 000 when the phase IV study was excluded).

The post-launch study did not report asystole and the phase IV trial did not report death; one can then be 95% confident that an asystole with propofol anaesthesia does not happen more often than 35 times in 10 000 patients, and that not more than 12 deaths caused by bradycardia happen in 100 000 propofol anaesthetics.[25]

## ESTIMATION: RATIOS BETWEEN ABSOLUTE RISKS OF DIFFERENT LEVELS OF HARM

In controlled trials one of 154 bradycardic episodes led to an asystole (table 2). Across all case series, including the review of 27 studies, an average of 240 bradycardias led to one asystole. In the phase IV trial alone, 623 bradycardias led to one asystole. Death was not reported in controlled studies or case series, therefore calculation of a ratio between major harm and disaster is not possible.

In observational reports (case reports and spontaneous reports to drug monitoring centres) approximately four bradycardias led to one asystole and one-third of asystoles were fatal (table 3). Asystole after propofol-induced bradycardia was 43 times more likely to be reported in observational reports than in controlled trials.

## QUALITATIVE ANALYSIS OF PUBLISHED REPORTS

Bradycardic complications occurred after induction, during or at the end of propofol anaesthesia. An abrupt, unpredictable decrease, or a progressive slowing of the heart rate, and sudden cardiac arrests were reported. Associated complications involved

tonic–clonic movements,[64] arrhythmia of unknown type,[36] junctional rhythm,[63 64] supraventricular bradycardia,[65] recurrence of asystole,[67 70] and intermittent episodes of heart block.[70]

Treatment of bradycardic events consisted in most cases of i.v. administration of anticholinergics, but also catecholamines,[7 51 52 59] precordial chest thump[65] and external cardiac massage.[36 59 63 72] Resistance to both i.v. atropine[7 51 52 59 65] and isoprenaline[7] was reported. In several reports heart rate normalization occurred after stopping the propofol infusion.[7 51 52 66] Several bradycardic episodes resolved spontaneously. The longest duration of asystole in surviving patients was 45 s.[64]

Several factors, alone or in combination, were coincident with bradycardic complications during propofol anaesthesia and were therefore suspected in the original reports to be jointly responsible for the negative outcome: surgical stimulation,[9 36] lack of surgical stimulation,[63 67] extradural anaesthesia,[51] previous syncope,[7 64 67] preoperative conduction abnormalities,[57 71] fentanyl,[8 63 65] suxamethonium,[35 62 65] atracurium,[8] beta-blocker,[61 70] ornipressin,[8] neostigmine,[70] any factors or drugs potentiating vagal stimulation,[19 68–70 72 73] absence of vagal stimulation,[63] too light anaesthesia,[76] insufficient prophylactic dose of atropine[48 50] and an individual susceptibility to propofol.[63 65] Most authors concluded that a prophylactic anticholinergic may be indicated in the presence of any risk factor if propofol is to be used.

## Discussion

We have described a new approach to adverse event reporting. The focus was on one particular complication with one particular drug.

The three main results of this study are of both methodological and clinical importance: first, a systematic approach to adverse event reporting, taking into account all types of reports with data of different strengths of evidence and both quantitative and qualitative analysis of the extracted data is possible; second, the additional risk of bradycardic events with propofol anaesthesia is finite, compared with other anaesthetic regimens; third, bradycardia with propofol is potential major harm.

Information on propofol anaesthesia and bradycardic events came from different sources. First, the biological basis for propofol-induced bradycardia was supported by several experimental animal and human studies. A plausible physiopathological mechanism explaining the occurrence of an adverse event during or after exposure to the treatment in question supports a causal association between adverse event and treatment.

Second, combined analysis of controlled trials showed a statistically significant difference between propofol and other anaesthetics. In non-ophthalmological settings the additional risk of bradycardia with propofol was approximately 9% (number-needed-to-harm 11.3) compared with other anaesthetics. In these studies the average risk of a bradycardic event in controls was less than 7%. In paediatric strabismus surgery where all children received prophylactic anticholinergics, the ability of propofol to produce a bradycardia caused by the OCR was even more pronounced; one of four children treated with propofol will have a bradycardic episode which would not have happened with another anaesthetic. In these latter studies the average incidence of bradycardia in controls was twice as high as in non-ophthalmological settings. This sensitivity analysis was another example of the clinically important relationship between the risk of an outcome without intervention and the number of patients needed to be treated with the intervention in order to produce such an outcome.[86] Although there is no way of assessing the risk for an individual patient, these results may influence clinicians' choice of interventions for particular groups of patients. These data strongly suggest that propofol is very likely to increase the incidence of bradycardic events compared with other anaesthetic regimens in any clinical setting with an increased risk of bradycardia.[87]

Third, the post-marketing surveillance study of propofol, although including almost 26 000 patients, did not contribute importantly to this analysis. This large but uncontrolled study was praised as having the unique advantage of systematically collected information, and was therefore presumed to reflect adequately the incidence of clinically significant adverse events.[60] However, the two published analyses of this trial did not agree. While a very low incidence of bradycardia (0.4%) but two cardiac arrests were reported in one,[60] the incidence of bradycardia was 10 times higher but no cardiac arrests reported in the other.[61] These differences challenge the reliability of these reports. Compared with controlled studies bradycardia was 3–4 times and asystole 19 times less likely to be reported in this case series, and four times as many bradycardias were necessary to produce one asystole (table 2). Only after combination with data from other series did absolute risk and ratios come closer to data from controlled trials. Drawbacks of phase IV studies have been pointed out previously.[88]

Fourth, in this analysis we used both published case reports and spontaneous reports to drug monitoring centres not only for description of a new or very rare adverse event [89] but to estimate the frequency of disaster. The majority of uncontrolled observations on adverse events are examples of the most dramatic though rare clinical scenarios imaginable. Indeed, published case reports are expected to draw attention to important clinical situations, unusual clinical phenomena and complications.[90] Therefore, in such reports ratios between different levels of harm are obvious overestimations of the clinical reality. But these reports are often the only source, which makes it possible to establish a ratio between major harm and disaster. Observations enabled a link between all three levels of harm to be made.

There is strong evidence that bradycardia is more likely to happen with propofol than with other anaesthetics. The question then is how serious is propofol-induced bradycardia? One response is to interpret it as minor harm, trivial and of no clinical importance. Such a response may not be correct. The prior hypothesis that propofol-induced bradycardic events may be an example of a continuum was supported consistently by data from all types of study. This implies that bradycardia during propofol anaesthesia cannot be discounted as minor harm but should be classified as potential major harm. Therefore, major harm and consequential disaster cannot be ignored and their likelihood has to be estimated. There is strong evidence from controlled trials that the incidence of asystole may be of the order of 15 in 10 000 patients receiving propofol anaesthesia. Uncontrolled series gave estimates with less strong evidence; the numbers were 0.8, 6.9, 11.5 and at most 35 asystoles per 10 000 patients, respectively. These numbers are difficult to interpret because of the lack of a comparator. The number-needed-to-harm calculation is more powerful because it enables comparison of the treatment in question with a control, in this case with another anaesthetic. Based on controlled studies, one of 660 patients undergoing propofol anaesthesia may have an asystole caused by propofol, who would not have had such a major complication in the same clinical setting with a different anaesthetic.

The next question is, what is the likelihood that propofol-induced asystole leads to death? Asystole was not always fatal. Several spontaneous restorations of sinus rhythm were described, but on some occasions treatment included catecholamines and external chest massage. Propofol-related bradycardia and asystole may indeed be of minor clinical importance if occurring in healthy subjects and adequately managed.

Different potential quantitative scenarios may be described. Death occurred only in observational reports. Ratios suggested that in the worst situation one-third of propofol-induced bradycardias may lead to an asystole, and that one-third of all asystoles may be fatal. In a worst-possible scenario with the most disastrous constellation of risk factors, these ratios from observational reports, together with a 15% absolute risk for bradycardia from controlled trials (strabismus surgery excluded), would translate into an incidence of 128 deaths in 10 000 propofol anaesthetics. However, the ratio between bradycardia and asystole in observational reports seemed to be a 43-fold overestimation compared with controlled trials. The most likely true ratio between propofol-induced asystole and death may then equal the observation-based ratio times this overestimation factor (i.e. 3.3 times 43 or one death after 112 asystoles). This corrected asystole–death ratio together with the absolute risk for asystole in controlled trials (one in 660 propofol anaesthetics) translates into 1.4 bradycardia-related deaths per 100 000 propofol anaesthetics. This number is in agreement with the rule-of-three estimation from the phase IV trial (at most 12 deaths in 100 000). This number is also in agreement with the estimate that one death attributable to any type of anaesthetic occurred in 20 000 operations in New South Wales between 1984 and 1990.[91] Death caused by bradycardic complications during propofol anaesthesia would then constitute approximately one-fifth of all anaesthesia-related deaths.

What clinical lessons can be drawn from this analysis? According to the manufacturer's data sheet, propofol should be given by those trained in anaesthesia or, where appropriate, doctors trained in the care of patients in intensive care. Severe bradycardia and asystole as possible complications of propofol are mentioned and the manufacturer suggests the prophylactic use of anticholinergics in patients at particular risk for bradycardia, and advises against the use of propofol for induction of anaesthesia in children less than 3 yr of age. These statements are supported by this study. Some comments may, however, be appropriate.

First, despite prophylactic anticholinergics the risk of bradycardia with propofol may still be considerable.[7–9, 35, 39, 40, 43, 44, 47, 48, 50, 51] Several reports suggested an inadequate response of propofol-induced bradycardia to atropine.[7, 51, 52, 59, 65, 80] Especially in children, prevention and treatment of bradycardia with atropine is controversial.[92] In this context, the suggestion that the prophylactic dose of atropine should be increased seems to be inappropriate.[48, 50]

Second, a stable heart rate accompanied by a decrease in cardiac output and systemic vascular resistance may result in inadequate peripheral perfusion pressure and oxygen delivery.[27] In young children cardiac output is more rate-dependent than in adults because of a limited ability to increase myocardial contractility.[93] The frequency of bradycardia during anaesthesia in children increases with both decreasing age and poorer ASA physical status.[94] There is evidence that propofol decreases heart rate more in children less than 2 yr of age compared with older children.[53] The pragmatic question is then, what happens to a young child who is very ill and who receives a long-term propofol infusion? Five of seven seriously ill ICU children who developed refractory bradyarrhythmia after prolonged propofol sedation were between 4 weeks and less than 3 yr old; in four the outcome was fatal.[10–12]

Third, physicians' perception of frequency and severity of harm together with their skills to treat major complications and to prevent a disaster may have an important impact on judging the risk:benefit of treatments. For instance, bradycardia caused by OCR has been recognized as an important intraoperative complication of strabismus surgery.[16, 95–96] However, two of seven published RCT comparing propofol with another anaesthetic in paediatric strabismus surgery did not report any information on the presence or absence of the OCR.[97, 98] The other five studies reported a much higher incidence of the OCR with propofol than with other anaesthetics despite prophylactic anticholinergics, but none questioned the indication for propofol in this setting.[39, 40, 44, 48, 50] Also, estimate of the asystole–death ratio of propofol may be perceived as being extremely low and therefore of no importance. However, this ratio describes only deaths caused by bradycardia-related complications during propofol anaesthesia. Inclusion of other possibly propofol-related deaths, such as cardiovascular collapse,[17] would have given a less favourable estimate. Most bradycardias and asystoles seem to have been adequately managed by anaesthetists, including resuscitation measurements such as i.v. catecholamines and external chest compression. The same quantity and severity of potential major and major harm in hands of physicians not used to such resuscitation techniques would probably have given different results.

Finally, the first contraindication to any drug is lack of indication.[92] Propofol anaesthesia is by no means a treatment without alternatives. It would therefore be helpful to identify both the subgroups most likely to profit from the beneficial characteristics of propofol and the subgroups at particular risk of complications. For instance, faster recovery and decreased incidence of postoperative nausea and vomiting after propofol anaesthesia are unlikely to be of clinical relevance in every setting.[99–101] Results from the sensitivity analysis, together with data from different reports, suggest that the indications for propofol should at least be questioned in the presence of conduction abnormalities,[36,57,71,74] heart rate lowering medications such as beta-blockers,[61,70] procedures with an increased risk of bradycardia,[87] including squint repair,[14] and laparoscopies,[32,43,69,102] and in very sick, old or young patients.[10–12,17,53,74,84,103]

This article has described an approach to adverse events which showed a biological progression. The example used was propofol bradycardia, asystole and death. It would be misleading to use this hazard out of context. Clearly there are many other hazards in anaesthesia which need to be considered; not all are as well documented. This model may be useful to allow us to be more precise about the other hazards.

# Phantom pain and sensation among British veteran amputees

S. W. WARTAN, W. HAMANN, J. R. WEDLEY AND I. MCCOLL

## Summary

Using a mail-delivered questionnaire, we surveyed 590 veteran amputees concerning phantom pain, phantom sensation and stump pain. They were selected randomly from a population of 2974 veterans with long-standing limb amputation(s) using a computer random number generator. Eighty-nine percent responded and of these, 55% reported phantom limb pain and 56% stump pain. There was a strong correlation between phantom pain and phantom sensation. The intensity of phantom sensation was a significant predictor for the time course of phantom pain. In only 3% of phantom limb pain sufferers did the condition become worse. One hundred and forty-nine amputees reporting phantom pain discussed their pain with their family doctors; 49 were told that there was no treatment available. Transcutaneous electric nerve stimulation, analgesics and non-steroidal anti-inflammatory drugs were satisfactory methods for controlling phantom limb pain. (*Br. J. Anaesth.* 1997; **78**: 652–659).

**Key words**
Pain, phantom limb. Analgesia, audit.

Knowledge of the persistence of sensation in a limb which has been removed must be as old as survival from amputation. Nevertheless, it was not until 1551 that the French military surgeon Ambroise Pare recorded the condition clearly when discussing amputations.[1] In 1871 Silas Weir Mitchell published his article "phantom limbs" and gave us this term which has had universal usage.[2] The phantom limb can be either painless (termed phantom limb sensation) or painful (phantom limb pain).

Virtually all amputees have various types of persistent phantom sensations.[3] The relation of these sensations to phantom pain is still not clear. The frequency of chronic phantom limb pain has been a matter of debate. It ranges between 1% and 98% in various studies.[4–8] One explanation for an apparent low incidence is probably the poor therapeutic consequences of treatment.

The aim of this investigation was to establish the incidence and time course of phantom limb and stump pain in long-standing amputees, to determine if there is a link between phantom sensation and phantom pain, and to examine the choice and effectiveness of treatment.

## Patients and methods

### POPULATION SURVEYED

The British Limbless Ex-Servicemen's Association (BLESMA) supplied a list of all 2974 members. Members of BLESMA are mainly old veterans with limb amputation(s) from World War II, the Falklands war and a few survivors from World War I. We selected randomly 590 members (approximately a one in five sample) to receive the questionnaire using a computer random number generator. All individuals selected were male amputees. A pilot study of 30 questionnaires was carried out before the main study to assess the rate of response and test the clarity of the questionnaire. The response for the pilot study was 85%.

### THE QUESTIONNAIRE

The survey instrument shown in figure 1 consisted of four pages which was a modification of the questionnaire used by Sherman, Sherman and Parker.[4] Each questionnaire was sent with a stamped addressed envelope and a personally addressed covering letter briefly defining phantom pain, phantom sensation and stump pain, and this was repeated at the beginning of relevant sections in the questionnaire. The covering letter included a clear request for all recipients to respond regardless of the presence or absence of phantom or stump pain.

Explanation of the method to rate pain was given at the beginning of the questionnaire. The same method was used to rate the uncomfortable phantom sensation. Questions required yes/no or do not know, rating scale or short answers. The questionnaire consisted of the following sections.

### *Patient characteristics and amputation history*

Questions requested information on age, sex, reason for amputation, number of years since amputation, site of amputation, presence or absence of pain in the limb before amputation and use of prostheses.

**AMPUTEE QUESTIONNAIRE** 1

Our Ref

TO RATE PAIN *When asked about how much pain you feel, please rate the amount of pain on a scale which starts at 0 (NO PAIN) and continues up to 10 (UNBEARABLE PAIN) The higher the number, the greater the pain (Please answer with one digit only)*

DNK ☐ Means Do Not Know

1 Your age ________

2 Your sex M ☐ F ☐

3 About your amputation

a Reason for amputation 1 Injury due to war or enemy action ☐
2 Peace time injury ☐

b Number of years since amputation ________

c Which limb(s) was removed?
Right arm ☐ Right leg ☐ left arm ☐ Left leg ☐

d Do you still have the knee or the elbow of the limb that was removed? Yes ☐ No ☐
If you have more than one limb amputation, please specify
________________________________

4 BEFORE the amputation, did you have pain in the part of the limb to be removed? Yes ☐ No ☐ DNK ☐
If you have more than one limb amputation, please specify
________________________________

5 Do you have an artificial limb? Yes ☐ No ☐

If Yes a Do you use your artificial limb regularly?
Yes ☐ No ☐ DNK ☐

b How many hours per day do you use it? ______

If No why not? ________________________________

2

6 When you get a headache

a On the scale of 0-10, how much pain do you have before you take medicine? __________

b How long do you wait before taking medicine (in hours)? _______

STUMP PAIN (ASKING ABOUT PAIN IN THE REMAINING PART OF THE LIMB I E. NOT PAIN FELT IN THE REMOVED PART OF THE LIMB).

7 Does your stump hurt? Yes ☐ No ☐ DNK ☐

If Yes a How frequently (e g how many days per month on average)? ________________

b On the 0-10 scale, what is the usual amount it hurts?
________________

c Have you had treatment for the pain int he stump?
Yes ☐ No ☐ DNK ☐
If Yes Please specify
________________

d Do you take medicine for the pain in your stump?
Yes ☐ No ☐ DNK ☐

PHANTOM SENSATION NOT PHANTOM PAIN OR STUMP PAIN

8 Do you have any sensation from the parts of the limb that was removed (phantom not stump)? Yes ☐ No ☐ DNK ☐

If Yes a What part or parts of the phantom do they come from?
________________________________

b Do the sensations ever make you a little uncomfortable (almost but not quite hurt)?
Yes ☐ No ☐ DNK ☐

c We would like to know how strong the non-painful sensations are If these sensations were painful, how strong would you rate them on the 0-10 scale? ________

3

PHANTOM PAIN ONLY (PAIN FELT IN THE REMOVED PART OF THE LIMB).

9 After your amputation, did you ever have any pain at all in the part of the limb that was removed? Yes ☐ No ☐ DNK ☐
If No go to the question number 10

If Yes

(a) Over the the months (or years) following the amputation, did the phantom pain
1 Go away? ☐
2 Decrease greatly? ☐
3 Remain the same? ☐

(b) How often do you have phantom pain?
1 Few times per hour? ☐ 2 few times per day? ☐
3. Few times per month? ☐ 4 Few times per year? ☐
5 All the time? ☐

(c) When the pain comes, how long does it last?
Seconds ☐ Minutes ☐ Hours ☐ Days ☐
Weeks ☐ Months ☐ Variable ☐

(d) What part or parts of the phantom do they seem to come from?
________________________________

(e) What do they feel like? ________________
________________________________

(f) On the 0-10 scale, what is the worst it ever hurt(s)? ________
(g) On the 0-10 scale, what is the least it hurt(s)? ________
(h) On the 0-10 scale, what is the usual amount it hurt(s)? _____

(i) Did you ever talk to a doctor about the pain? Yes No
If Yes what did he tell you? ________________
________________________________
what did he do? ________________

(j) Did the pain ever get bad enough to ask for treatment (phantom pain NOT stump pain)? Yes ☐ No ☐

4

If Yes

(1) Was your treatment one or more of those methods
Sympathectomy (a nerve block near the spine) ☐
Electrical stimulation machine ☐
Operation on the stump ☐
Injection of the stump ☐
Others (please specify) ________________

(2) Were you satisfied with your treatment?
Yes ☐ No ☐
If Yes please specify which method?
________________________________

(K) Do you ever take medicine for the phantom pain?
Yes ☐ No ☐
If Yes (1) What (include paracetamol, etc )?__________
________________________________

(2) Are you satisfied with your medicine?
Yes ☐ No ☐ DNK ☐
If Yes please specify which medicine ______
________________________________

(l) When the pain comes, do you take alcohol to help the pain?
Yes ☐ No ☐ DNK ☐

If Yes Does it help easing the pain at all?
Yes ☐ No ☐ DNK ☐

(m) On the 0-10 scale, how much will the pain have to be before you want treatment? ________________

(n) Do you want treatment for the phantom pain?
Yes ☐ No ☐ DNK ☐

If No or DNK. Why? ________________

10 Did you need help to fill in the questionnaire? Yes ☐ No ☐

**THANK YOU VERY MUCH FOR ANSWERING THIS QUESTIONNAIRE**

*Figure 1* The four-page amputee questionnaire.

## *Pain sensitivity and attitude towards use of medical treatment for pain not related to the amputation*

We wished to ascertain if respondents who request treatment for their phantom pain were different in their sensitivity to pain or in their attitude towards medicine than respondents not requesting treatment. Questions on the intensity and duration of headache before taking medicine were asked in this section.

## *Stump pain*

Questions asked if the stump hurt, the frequency and intensity of pain, methods of treatment and use of medication.

### *Phantom sensation*

This section was intended to differentiate between the benign phantom sensation and the uncomfortable sensation. Information on location and intensity of phantom sensation when uncomfortable were asked to relate them to the painful phantom.

### *Phantom pain*

This was the largest section in the questionnaire. Questions asked about the presence of phantom pain, time course, frequency and duration of attacks, location and description, intensity of pain and if respondents with phantom pain ever asked their doctors about the pain and the response to their question. A series of questions asked about the different methods of treatment offered when the respondent requested treatment for the phantom pain and satisfaction with treatment, including self-medication and alcohol. A question to gauge the intensity of phantom pain before requesting treatment was asked to relate to similar questions regarding headache. Reasons for not requesting treatment for phantom pain were explored by another question.

### *Help*

As most members of BLESMA are senior citizens, a question ascertained the reliability of the returned completed questionnaire by asking if the questionnaire was answered by the individual himself.

### STATISTICAL ANALYSIS

We used the statistical software, SPSS for Windows version 6.1, for analysis of our data. Student's $t$ test was used for comparison of the means of two groups of data measured on an interval scale, for example age. The Mann–Whitney $U$ test was used for comparison of the means of two groups of data measured on an ordinal scale, for example pain measurement scale. Chi-square tests were used for comparison of non-numeric data and frequency of occurrence; these tests indicate if a series of events occurred with equal frequency among several groups. Differences were considered significant if the probability ($P$) was equal to or less than 0.01. Statistical significance was used only as a guide towards determining the clinical significance of different patterns.

## Results

### RESPONSE RATE

Of the 590 questionnaires sent out, 10 were returned by the postal service as not delivered and 22 were returned by the addressee's relatives as members were either mentally not fit to answer or were deceased. Only 32 failed to respond. The total number of evaluable questionnaires returned was thus 526 (89%). This was achieved by sending two waves of questionnaires, 8 weeks apart. The second wave was sent only to non-responders, which increased the response rate from 81% to 89%. Forty-five respondents accompanied their completed questionnaires with letters containing further information and notes of thanks for our interest.

### RELIABILITY OF THE DATA

Only 10.7% of respondents needed help to complete the questionnaire. Most of the respondents who needed assistance accompanied their answers by comments explaining the reason, which were mainly because of instability of the hand, for example parkinsonism.

### SAMPLE CHARACTERISTICS

All respondents' amputations were of traumatic origin. Eighty-nine percent were sustained during active service. Median age and number of years since amputation were 73 and 50 yr, respectively. Approximately 87% of respondents had a lost limb(s) for the past 30–50 yr, few for even longer. Almost 50% of respondents had below knee amputation (table 1).

### PHANTOM PAIN AND STUMP PAIN FREQUENCY AND CHARACTERISTICS

Three-hundred and twenty-six respondents reported unambiguously the feeling of phantom pain, while 18 respondents were either not sure or were confusing phantom pain and stump pain despite the advice in our covering letter and questionnaire to clarify the difference. These 18 respondents were considered as not reporting phantom pain. Therefore, the frequency of phantom pain in 590 veterans surveyed was 55.2%, assuming the "best possibility" that all non-respondents had no phantom pain. Three-hundred and thirty-four respondents reported stump pain (56.6%), of whom 220 reported phantom pain and stump pain. Duration of stump pain was reported as a mean of 13 (SEM 0.65) days per month. Respondents were asked to rate the intensity of their pain on a 0–10 scale (0=no pain, 10=unbearable pain). Mean intensities of stump pain and phantom pain were 6.2 and 5.6, respectively ($P$=0.002). On the same scale the means of their least and worst phantom pain were 3.6 (SEM 0.15) and 7.8 (0.15), respectively. There were no significant differences in relation to stump pain intensity between respondents reporting phantom pain and respondents not reporting phantom pain (mean 6.1 and 6.5, respectively) ($P$=0.14).

*Table 1* Site of amputation. Note some respondents had more than one limb amputation

| Site | No. of respondents (%) |
|---|---|
| Above elbow | 10.3 |
| Below elbow | 8.5 |
| Above knee | 41.8 |
| Below knee | 47.7 |

*Table 2* Phantom pain description. Note some respondents reported more than one description

| Description | No. (%) |
|---|---|
| Stabbing | 24.3 |
| Pins and needles | 20.5 |
| Cannot describe the pain | 16.0 |
| Shooting (electric shock) | 12.8 |
| Cramping | 12.8 |
| Crushing | 10.1 |
| Burning | 9.4 |
| Abnormal position | 4.5 |
| Leg jumps | 4.5 |

Phantom pain disappeared completely in 52 (16%) respondents reporting phantom pain and decreased substantially in another 121 (37%), while it remained the same in 144 (44%) and even increased in nine (3%) respondents reporting phantom pain. One hundred and thirty-three (41%) respondents reporting phantom pain had a few attacks of pain every month, 81 (25%) fewer attacks per year, 53 (16%) had bouts of pain every day, 53 (16%) reported that the pain was always present and six (2%) reported a few attacks of pain every hour. Of those respondents whose phantom limb pain remained constant over the years, 58 (40%) were suffering pain attacks a few times per month, 39 (28%) reported that the pain was present continuously, 27 (19%) had a few attacks per day, 15 (10%) reported only a few attacks per year and only five (3%) reported a few attacks per hour. When the pain started, it lasted a few seconds or minutes in 116 (40%) respondents reporting phantom pain, hours in 87 (30%) and days in 17 (6%), and 70 (24%) reported that the pain was variable in duration with no pattern. The most common description of the phantom pain feeling was stabbing pain (24.3%) and pins and needles (20.5%) (table 2).

## PHANTOM SENSATION *VS* PHANTOM PAIN

Three-hundred and fifty-two respondents reported the feeling of phantom sensation (66.8% of total respondents) and of these 273 (77.6%) reported phantom pain and phantom sensation. The strong relation between phantom pain and phantom sensation was obvious (chi-square=107.3 with 1 df, $P<0.00001$). We did not ask if phantom sensation preceded phantom pain. Respondents were asked to rate the intensity of their benign phantom sensation on the 0–10 scale (analogous to the visual analogue scale for pain). Sixty-three (17.9%) respondents reported phantom sensation but no phantom pain; mean phantom sensation intensity was 3.2 (SEM 0.31). Mean intensity of phantom sensation in respondents reporting phantom pain was 5.4 (0.17). This was significantly higher than the mean of 3.2 (0.31) reported by respondents who never reported phantom pain (fig. 2). The linear relationship between intensity of the usual phantom pain and phantom sensation intensity is shown in figure 3. There was a strong correlation between location of phantom limb sensation and phantom pain (chi-square=1562 with 196 df, $P<0.000001$) (table 3). Sixty-seven percent (67%) of respondents reporting phantom pain and phantom sensation reported exactly the same location for both sensation and pain. There was no relation between phantom sensation and site of amputation. We found that the intensity of phantom sensation was a significant predictor of the course of phantom pain in the future (time course), that is whether the phantom pain disappeard, decreased, remained the same or increased in the years after amputation. Of respondents reporting phantom pain with a phantom sensation intensity of 5 or less on the 0–10 scale, 61% said their phantom pain either decreased substantially or disappeared completely in due course. On the other hand, in respondents reporting phantom pain whose phantom sensation intensity was 5.1 and higher, 69% reported continued experience of phantom pain with the same intensity, while 3.7% reported increased intensity of pain. No respondent from the former

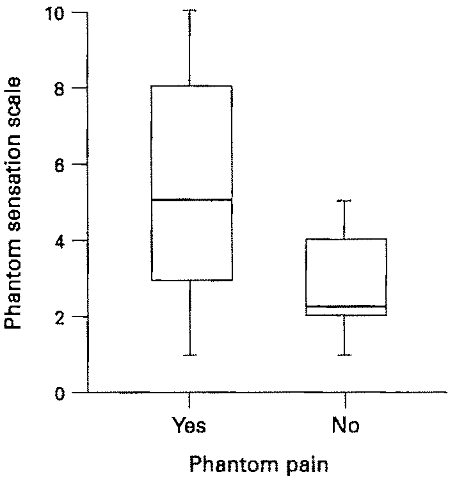

*Figure 2* Box plot showing intensity of phantom sensation in respondents reporting and not reporting phantom pain. The lower boundary of the box is the 25th percentile, and the upper boundary is the 75th percentile. The horizontal line inside the box represents the median. The whiskers are the largest and smallest values that are not outliers.

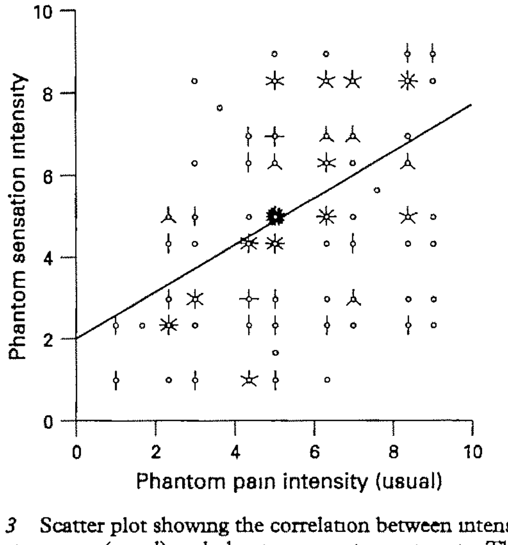

*Figure 3* Scatter plot showing the correlation between intensity of phantom pain (usual) and phantom sensation intensity. The number of petals in a sunflower represents the number of cases.

*Table 3* Site of phantom pain and phantom sensation. Note some respondents had more than one site of phantom limb pain and sensation

| Site | Phantom pain site (% of respondents) | Phantom sensation site (% of respondents) |
|---|---|---|
| Fingers/toes | 32 | 44 |
| Hand/foot | 45 | 46 |
| Wrist/ankle | 13 | 14 |
| Sole | 6 | 5 |
| Arm/leg | 16 | 12 |
| Elbow/knee | 6 | 4.5 |
| Near but not the stump | 7 | 2 6 |
| Old injury site | 1.8 | 1 |
| Whole arm/whole leg | 9 | 9 |

*Table 4* Relationship between phantom sensation intensity and phantom pain time course. PS=Phantom sensation, PP=phantom pain, %=percent of respondents

| PS intensity | PP disappeared | PP decreased | PP remained same | PP increased |
|---|---|---|---|---|
| 1–5 | 10.6% | 50.4% | 39% | 0% |
| 5.1–10 | 2.8% | 24.3% | 69.2% | 3.7% |

group reported increased pain intensity (chi-square=22.7 with 1 df, $P$=0.00001) (table 4).

In view of these significant relationships between phantom pain and phantom sensation, we were able to allocate respondents reporting phantom pain to one of three groups: group 1, 46 respondents reporting phantom pain with no phantom sensation (15% of respondents reporting phantom pain); group 2, 32 respondents reporting phantom pain and benign phantom sensation (10% of respondents reporting phantom pain); group 3, 237 respondents reporting phantom pain and uncomfortable phantom sensation (dysaesthesia) (75% of respondents reporting phantom pain). We found a significant difference between the three groups in relation to the time course of their phantom pain (chi-square=100.5 with 6 df, $P$=0.00001). Phantom limb pain disappeared or decreased in intensity in 39 (85%) respondents in group 1 in contrast with 21 (65.6%) and 103 (43.8%) respondents in groups 2 and 3, respectively. Only seven (15%) respondents in group 1 continued suffering phantom pain with the same intensity, compared with nine (28%) and 125 (53.2%) in groups 2 and 3, respectively (table 5).

One hundred and ninety-five (82%) respondents in group 3 experienced stump pain. This was significantly higher than the incidences in group 1 (28 (12%)) and group 2 (14 (6%)) (chi-square=16.6, with 6 df, $P$=0.0002). There was no significant difference in the intensity of stump pain or phantom limb pain between the three groups.

Phantom sensation intensity was significantly higher in group 3 (mean 5.7 (SEM 0.17)) compared with group 2 (2.6 (0.41)). There was a significant difference between the three groups in relation to phantom pain frequency (chi-square=31.9 with 8 df, $P$=0.0001). In groups 1 and 2, pain occurred mainly as a few attacks per year while in group 3 phantom pain was far more frequent, occurring as a few attacks every month. There was no difference between the three groups in their response to different methods of treatment.

### CORRELATION BETWEEN POSSIBLE PREDISPOSING FACTORS AND PHANTOM PAIN

There was no significant difference between those respondents reporting phantom pain and those not reporting phantom pain in relation to age at amputation (means 25.8 and 25.2 yr, respectively) ($P$=0.27). No significant difference was found between respondents reporting phantom pain and those not reporting phantom pain in relation to site of amputation (chi-square=5.5, 3 df, $P$=0.13) and pain in the limb before amputation (chi-square=10.6 with 4 df, $P$=0.3). The incidence of phantom limb pain was not higher in respondents who had more than one limb amputation (chi-square=0.007 with 1 df, $P$=0.93).

### POST-AMPUTATION PREDICTORS OF PERSISTENCE OF PHANTOM PAIN

There was a significant difference between respondents reporting phantom pain and not reporting phantom pain in relation to age (mean 70 and 72.4 yr, $P$=0.016). However, this difference was not clinically significant. There were no significant differences between respondents reporting phantom pain and those not reporting phantom pain concerning the use of a prosthesis ($P$=0.6) or number of hours per day the prosthesis was used (means 13.2, 13.6 h, respectively, $P$=0.1). Only 20 (3.8%) respondents did not use their prosthesis. The main reasons for not using it were stump problems (34%), ill health (24%) and clumsiness (22%), especially in upper limb amputees. Only 8% reported aggravation of phantom limb pain with the use of a prosthesis.

*Table 5* Relationship between the three groups of presentation of the sample and the time course of phantom pain. PP=phantom pain, PS=phantom sensation, %=percent of respondents reporting phantom pain

| | PP with no PS (Group 1) | PP with benign PS (Group 2) | PP with uncomfortable PS (dysaesthesia) (Group 3) |
|---|---|---|---|
| Respondents reporting PP | 46 | 32 | 237 |
| PP disappeared | 29 (63%) | 5 (15.6%) | 15 (6.4%) |
| PP decreased | 10 (21.7%) | 16 (50%) | 88 (37.4%) |
| PP remained same | 7 (15.2%) | 9 (28.1%) | 125 (53.2%) |
| PP increased | 0 (0%) | 2 (6.3%) | 7 (3%) |

### PAIN SENSITIVITY AND ATTITUDE TOWARDS USE OF MEDICAL TREATMENT FOR PAIN NOT RELATED TO THE AMPUTATION

There was no significant difference between respondents reporting and not reporting phantom pain concerning headache intensity before taking medication (means 6.4 and 6.1, $P=0.42$), and duration of headache before taking medication (means 2.2 and 2.0, $P=0.5$).

### PHANTOM PAIN TREATMENT

One hundred and forty-nine respondents reporting phantom pain discussed their pain with their family doctor. There was a significant difference in the duration, frequency and worst pain intensity between respondents discussing and respondents not discussing the pain. Respondents who reported phantom pain lasting hours, days or of variable pattern tended to discuss their pain (chi-square=24.8 with 4 df, $P=0.00005$). Their worst phantom pain intensity was significantly higher (mean 8.7) ($P<0.0001$). Respondents reporting phantom pain episodes of a few times every year were the least likely to discuss their phantom pain (chi-square=16.2, with 3 df, $P=0.001$). Forty-nine respondents who discussed the pain with their doctors were told that there was no treatment to help the pain. The remainder were told the following: 20 respondents "pain is expected after amputation"; 17 respondents "the pain is nerve pain"; eight respondents "the pain is in their mind"; 11 respondents "the pain will go away"; six respondents "the stump is the cause of phantom pain" and one respondent was told "this pain will never go away". Seventy-five respondents who discussed their phantom pain with their doctor were prescribed analgesics, 39 were offered nothing and only 17 respondents were referred to a pain relief clinic.

*Table 6* Methods used for treatment of phantom pain and patient satisfaction. Others=Cryotherapy, cordotomy, nerve block, ointments and hitting the stump with a wooden mallet. *All respondents who were offered no treatment returned the question "were you satisfied with your treatment?" unanswered

| Treatment type | Amputees received treatment | Amputees were satisfied with treatment |
|---|---|---|
| TENS | 26 (36%) | 11 (42.3%) |
| Operation on the stump | 12 (16.6%) | 5 (41.6%) |
| Injections of the stump | 11 (15%) | 1 (9%) |
| Sympathectomy | 8 (11%) | 3 (37.5%) |
| Acupuncture | 3 (4%) | 0 |
| Others | 15 (20.8%) | 0 |
| Nothing | 8 (11%) | N/A* |

*Table 7* Medication used for phantom pain treatment and patient satisfaction. Simple analgesics=paracetamol, compound analgesics=paracetamol and opioid, NSAID=non-steroidal anti-inflammatory drugs, anticonvulsants=carbamezapine, antidepressants=amitriptyline

| Type of medicine | Respondents using it | Respondents satisfied |
|---|---|---|
| Simple analgesics | 96 (53%) | 45 (47%) |
| Compound analgesics | 67 (37%) | 42 (63%) |
| NSAID | 27 (15%) | 20 (74%) |
| Anticonvulsants | 12 (6.6%) | 3 (25%) |
| Opioids | 10 (5.5%) | 4 (40%) |
| Antidepressants | 2 (1%) | 0 |
| Alcohol | 42 | 31 (74%) (helpful) |

Seventy-two respondents reporting phantom pain asked for treatment for their phantom pain: eight (11%) respondents were offered nothing and 26 (36%) received transcutaneous electric nerve stimulation (TENS), of whom 11 (42%) expressed satisfaction with the treatment, including three who reported that it partially helped and another two who reported that it was extremely helpful (table 6). There was no significant difference in phantom pain intensity between respondents who reported satisfaction and those who did not report satisfaction with (TENS) treatment. In eight respondents of those who were satisfied with TENS treatment, it was used in conjunction with other methods of pain control. However, they reported their satisfaction with TENS treatment alone. Other treatments included different operations on the stump in 12 (16.6%) respondents, injections of the stump in 11 respondents (15%) and sympathectomy in eight (11%) respondents. Reasonable satisfaction was reported with operations on the stump and sympathectomy, with low satisfaction from nerve blocks (table 6).

One hundred and eighty-two respondents reporting phantom pain were taking medication for their pain at the time of the study. Ninety-six respondents were taking simple analgesics (paracetamol); 45 (47%) reported satisfaction with the treatment. Compound analgesics (paracetamol with an opioid) were taken by 67 respondents, with 42 (63%) reporting satisfaction. Although only 27 respondents were taking non-steroidal anti-inflammatory drugs (including aspirin), 20 (74%) stated their satisfaction with its phantom pain controlling effect (table 7). Forty-two respondents took alcohol to help their pain, of whom 31 (74%) reported that it was helpful.

Two hundred and twenty-three respondents reporting phantom pain did not wish to be treated at present. Sixty-five (29%) of those respondents reported the pain was not bad enough to require treatment; 32 (14%) reported their pain was not frequent enough; 18 (8%) had no more pain; 26 (12%) reported that the results of treatment were not encouraging among the amputee community; 35 (16%) were used to the pain; 22 (10%) thought they were too old to try new treatments; and 17 (8%) feared the complications of various methods of treatment.

*Table 8* Stump pain treatment. Miscellaneous=hitting the stump, massage, creams, acupuncture

| Type of treatment | Respondents |
|---|---|
| Operation on the stump | 14 (18 7%) |
| TENS | 12 (16%) |
| Injections | 12 (16%) |
| Alterations of the artificial limb | 7 (9.3%) |
| Sympathectomy | 3 (4%) |
| Miscellaneous | 27 (36%) |

### STUMP PAIN TREATMENT

Only 75 (22%) respondents who reported stump pain received treatment (table 8). Interestingly, hitting the stump with a wooden mallet, which is described as the oldest method for stump pain treatment, was still used by several respondents. One hundred and eighty-three (55%) of the respondents reporting stump pain were taking analgesics.

## Discussion

This is the second largest survey on phantom limb pain and stump pain after the survey reported by Sherman, Sherman and Parker in 1984.[4] The results of our study are of interest in three aspects. First, it is the largest British survey on chronic pain related to traumatic limb amputation. Second, the long-standing amputees studied presented us with ample information to assess the time course of phantom pain and stump pain. Third, the excellent response provided reliable information to address the problems of phantom limb and stump pain in amputees.

In designing a mailing survey, the length of the questionnaire in relation to the number of questions asked and the total number of pages sent to the potential respondent, is a major concern. In our study, which consisted of a relatively long questionnaire, we achieved a response rate of 89%. This highlights two interesting points: first, the response to a survey is related directly to the impact of the subject under investigation on the individual's life; second, the characteristics of the sample play an important role in their response, for instance the age of the amputees we studied. As war pensioners we anticipated that they have sufficient spare time to respond.

Fifty-five percent of respondents reported unambiguously the experience of phantom pain with a mean pain intensity of 5.6 on a 0–10 scale; this suggests that a considerable number of amputees suffer from this perplexing pain at least at some stage after amputation. Our result is similar to the 54% frequency reported in 1987 by Krebs and colleagues who followed-up 86 patients with limb amputations caused mainly by peripheral occlusive vascular diseases for 7 yr.[5] Riddoch reported a similar frequency in 1941 in traumatic and surgical amputations.[7] It seems that phantom pain has the same rate of occurrence in traumatic and other forms of amputation and it may be a persistent condition that stays with the amputee for the remainder of life as approximately 50% of respondents reporting phantom pain were in the worst pain for a long duration.

Our results showed a similar frequency of stump pain compared with phantom limb pain. However, stump pain intensity was higher. The six most common causes of stump pain are: prosthogenic, neurogenic, arthrogenic, sympathogenic, referred and abnormal stump tissue.[9] Most of these causes can be treated. It seems that we need to address the problem of stump pain and phantom limb pain when treating limb amputation related pain.

Phantom pain may be expected to decrease or even disappear with time.[10] Almost 50% of respondents suffering from phantom pain reported a substantial decrease to complete alleviation of pain, suggesting that this could be true in some cases of long-standing amputations. However, 47% of amputees continued to experience pain, indicating the seriousness of the problem in the amputee population.

Approximately 50% of respondents reporting phantom pain discussed their pain with their family doctor. These respondents suffered the most pain for long durations with frequent attacks. One might expect that amputees with phantom pain of such characteristics would be referred to pain clinics where they may have greater access to therapies provided by specialists in the field of chronic pain management. However, only 17 amputees were referred to such centres. This may prevent patients from receiving adequate care. There is clear evidence that phantom pain is not an easy condition to manage even when therapy is provided by specialists. The problem is not if patients try therapies but if they receive them in a structured manner.[11]

Sherman, Sherman and Parker[4] reported in 1984 the use of TENS in 20 of 2145 (0.9%) amputees with phantom pain. TENS at that time was expensive and rarely available outside pain clinics. At present they are used by physiotherapists, nurses, palliative care specialists and pain clinicians. Our finding that of the 72 amputees with phantom pain who requested treatment, 26 (36%) received TENS of whom 11 (42%) experienced satisfactory pain relief is significant as we assume that at least a few of those had the treatment for more than 1 yr. These patients were not satisfied with other therapies or even concomitant therapies, but only with TENS. This does not suggest satisfaction with treatment in general or the quality of care or the carers. It is also a common experience that if TENS is ineffective, it is discontinued even if it is not returned. TENS is often discontinued despite efficacy because it is inconvenient or irritant, or the efficacy is not great enough to outweigh the inconvenience or intrusive sensation. TENS is a simple, safe and re-usable first-line treatment.[12] It can be used long term with no risk of serious adverse effects.[13] Perhaps the principal message from these results is that TENS is at least as effective as any other therapy and as it is neither destructive nor expensive, it should be the treatment of first choice.

It seems that analgesic medicine has a useful role in the relief of phantom pain. Paracetamol was the most commonly used drug. However, the synergistic action of paracetamol and an opioid showed increased satisfaction with pain relief. NSAID were successful in 74% of 27 patients in our sample. In acute pain there is a growing body of evidence in favour of a central mechanism for the anti-inflammatory and analgesic effects.[14] NSAID have been shown to exert a direct spinal action by blocking the excessive sensitivity to pain (hyperalgesia) induced by activation of spinal glutamate and substance P receptors.[15] There is also strong evidence that NSAID work by changing 5-HT concentrations in the central nervous system.[16] Information on chronic pain is not yet available.

The development of phantom limb pain after amputation has been the subject of much discussion. Our work has added a new finding to the debate, namely the strong correlation between intensity of mechanical phantoms and severity of phantom limb pain. Therefore, it appears that nervous activity responsible for either sensation is mediated along the same central pathway.

The first point of convergence from tactile and nociceptive primary afferents is at the level of the wide dynamic range neurones in the dorsal horn. It is from this level rather than from higher levels of the pain pathway that central phantom limb pain is most likely to originate; there is animal evidence that after experimental division of the dorsal columns there is very little adaptive reorganization of the cerebral cortex.[17]

Yang and colleagues[18] and Aglioti, Bonazzi and Cortese[19] observed that phantom limb pain may be projected to parts of the body from parts of the body previously serving the amputated limb. These authors interpreted their findings as caused by cortical plasticity; their findings are, however, also consistent with the well documented concept of reorganization involving sprouting into adjacent laminae in the somatotopically organized dorsal horn[20] after transection of peripheral nerves in animal experiments.[21] In essence, somatic central phantom limb pain may be a condition of pathologically increased gain in the wide dynamic range neurones.

We conclude that phantom pain is a major problem as 47% of suffering amputees reported continuing pain. The more treatable stump pain was equally common. TENS, analgesics and NSAID seemed to have a role in the treatment of phantom limb pain. The relation between phantom pain and phantom sensation is still not clear and requires further investigation.

# Low molecular weight heparin associated with spinal anaesthesia and gradual compression stockings in total hip replacement surgery†

C. M. Samama, F. Clergue, J. Barre, A. Montefiore, P. Ill, K. Samii and the Arar Study Group

## Summary

The benefit/risk ratio of administering heparin during spinal anaesthesia in patients undergoing total hip replacement (THR) has not been studied widely. We conducted a prospective, randomized, double-blind study to compare low molecular weight heparin (LMWH) for 10 days and placebo in patients undergoing THR performed under spinal anaesthesia associated with gradual compression stockings. Efficacy was assessed by systematic bilateral ascending venography on day 10±2 in a sequential analysis. Among the 170 patients enrolled, data were available in 153 patients. In the LMWH group (*n*=78) the total incidence of deep vein thrombosis (DVT) was 14.1% compared with 37.3% in the placebo group (*n*=75) (*P*=0.0016). No gross neurological sequelae were observed during the study. This study showed that the addition of LMWH in patients undergoing THR under spinal anaesthesia and wearing gradual compression stockings significantly decreased the incidence of venogram-proved DVT. (*Br. J. Anaesth.* 1997; **78**: 660–665).

**Key words**
Surgery, orthopaedic. Anaesthetic techniques, subarachnoid. Complications, deep vein thrombosis. Blood, anticoagulants, heparin.

It is well recognized that patients undergoing total hip replacement surgery (THR) are at high risk of developing venous thromboembolism. Fatal pulmonary embolism may occur in 1–5% of these patients.[1–3] Without thromboprophylaxis, incidences of venogram-proved deep vein thrombosis (DVT) of up to 50% have been reported.[4] Several clinical studies have demonstrated the effectiveness and high benefit/risk ratio of low molecular weight heparins (LMWH) in the prophylaxis of DVT,[4–7] and meta-analyses have confirmed their role in patients undergoing orthopaedic surgery.[8 9] Central neural block (extradural anaesthesia or subarachnoid anaesthesia) is used widely in orthopaedic surgery. Spinal anaesthesia has been shown in fracture and elective hip surgery to moderately reduce postoperative DVT.[10] Winter-Christensen and colleagues[11] showed in 55 THR patients that extradural anaesthesia alone was as effective in preventing DVT as unfractionated heparin in combination with extradural anaesthesia. However, the association of heparin and central neural block remains questionable because of the potential risk of spinal haematoma.[12] A consensus conference, held in Europe in 1991, suggested that the benefit/risk ratio of this association should be reassessed.[13] This prospective, randomized, double-blind study was therefore designed to assess the benefit/risk ratio of LMWH in addition to spinal anaesthesia and gradual compression stockings in THR surgery.

## Patients and methods

We considered eligible for the study consecutive patients aged more than 18 yr, weighing 45–95 kg, undergoing primary THR surgery under regional anaesthesia (subarachnoïd block and catheter removed at the end of the surgical procedure), wearing gradual compression stockings (started the day before surgery).

Exclusion criteria were: re-operation for THR, surgery under general anaesthesia, patients under nail extension before surgery, history of DVT, pulmonary embolism, or both, hepatic or renal insufficiency, lung or heart failure, ASA status more than III, haemorrhagic disorders contraindicating the use of antithrombotic drugs (active ulcerative disease, uncontrolled arterial hypertension, stroke within the previous 6 months or other known haemorrhagic disorders), occurrence of a bloody tap during spinal

puncture, platelet count less than $100 \times 10^9$ litre$^{-1}$, history of heparin-associated thrombocytopenia or allergic reactions to heparin, low molecular weight heparin or to radiocontrast agents, and women with childbearing potential. In addition, patients were not included if they received heparin for more than 24 h before surgery, oral anticoagulant treatment within 3 days, antiplatelet drugs within 8 days or non-steroidal anti-inflammatory agents within 2 days before surgery.

A prospective, double-blind, randomized, placebo-controlled study was carried out on two parallel groups of patients in 11 participating centres. Patients were selected to enter the study before the surgical procedure if they completed the pre-screening criteria, and randomization was made at the end of the surgical procedure at 6±1 h after spinal puncture. This procedure aimed to exclude pre-screened patients needing general anaesthesia during surgery. Patients were allocated to receive subcutaneously, once daily, for 10±2 days either LMWH or placebo. All patients underwent daily clinical evaluation and systematic bilateral ultrasonography of the lower extremities on treatment days 3 and 6. All patients underwent systematic bilateral ascending contrast venography on day 10±2 after surgery, or earlier if indicated. Patients with negative venography on day 10±2 were then given, a once-daily dose of LMWH s.c. (open label enoxaparin 40 mg) for 28 days after hospital discharge as long-term prophylaxis because these patients were considered at high risk of DVT within the month following surgery.[13] Those with evidence of DVT detected by the investigator on systematic venography were treated using the usual therapeutic regimens. All patients were scheduled for a 3-month post-surgery follow-up. All clinical suspicions of a thromboembolic event during this follow-up period were documented by ultrasonography or venography for DVT, and by ventilation–perfusion lung scan or angiography for pulmonary embolism.

This study was conducted in accordance with the Declaration of Helsinki, European Good Clinical Practice and French Law. The study was approved by the Ethics Committee of La Pitié-Salpêtrière Hospital, Paris, France, and written informed consent was obtained from all patients before randomization.

### THERAPEUTIC REGIMENS

Eligible patients operated on under spinal anaesthesia and wearing gradual compression stockings (Ted stockings provided by Kendall) were allocated randomly to receive either LMWH or placebo, using a computer-generated randomization schedule, which was equilibrated by study centre and balanced in blocks of four patients. Patients in the LMWH group received, once daily, enoxaparin 40 mg (0.4 ml) s.c., corresponding to 4000 iu of anti-Xa, for 10±2 days. Patients in the control group received subcutaneously, once daily, a 0.4-ml injection of saline s.c. (3.6 mg of sodium chloride in 0.4 ml of infusion water) for 10±2 days.

### OUTCOME MEASURES

The primary efficacy outcome was defined as the occurrence of postoperative venous thromboembolic complications (confirmed DVT or pulmonary embolism) during the 10±2 postoperative days after surgery. The primary study conclusions for efficacy were based on intent to treat analysis in patients with adequate radiographic examinations reassessed by an independent central Reading Committee for venographies, angiographies or lung scans, and if necessary by a third expert from the Data and Safety Monitoring Review Board. All venograms were evaluated by two independent radiologists who were unaware of the treatment. The venograms were considered positive when a constant intraluminal filling defect was present in at least two different positions. DVT was classified as proximal when the thrombus was in the popliteal vein or above, and as distal when the thrombus was in the calf vein. Muscle veins were also taken into account in addition to DVT for safety purposes considering the estimated risk of developing a visualized thrombus in a placebo group. All patients with proximal, distal or muscle thrombi were considered as having DVT.

The secondary efficacy and safety outcomes were defined as occurrence of clinically suspected venous thromboembolic events, major or minor haemorrhagic episodes or any other serious adverse event (including death, life-threatening events and events that resulted in prolonged hospitalization or re-hospitalization) within the 3-month follow-up.

Haemorrhage was classified as major if it was overt and associated with either a decrease in haemoglobin of 2 g dl$^{-1}$ or more, a need for transfusion of 2 u. or more of packed red blood cells, if it was retroperitoneal or intracranial, or if it led to surgical reintervention or death. Haemorrhage was defined as minor if it was overt but did not meet the other criteria for major haemorrhage. Intra- and postoperative blood loss was also calculated. The potential occurrence of spinal haematoma was assessed by daily patient examination performed by an anaesthetist during hospitalization. No systematic neurological assessments were required except in cases of clinical symptoms suggesting neural compression such as sensitive or motor deficit associated with back pain. The postoperative blood loss calculation was performed by the standardized method of Toy and colleagues.[14] Measures of wound haematoma width were recorded daily. Blood samples for measurement of haemoglobin concentration and platelet count were obtained before surgery, and on days 3, 6 and 10±2.

### STATISTICAL ANALYSIS

This study was conducted as a closed sequential trial. Sample size evaluation was based on the assumption of an expected incidence of DVT of 15% for the LMWH group and 25% for the control group. Considering a type I error of 5% and type II error of 20%, it was calculated that a total number of 500 patients (250 in each group) would be needed to detect such a difference. In this study the statistical

procedure was a sequential grouped analysis using the simple triangular test procedure[15] in which the final sample size is not fixed in advance. In this procedure, data concerning the primary efficacy endpoint were analysed after every 50 patients. In these conditions, the maximum final sample size could be a total number of 750 patients (375 patients in each group), corresponding to a maximum number of 15 inspections. Two statistical assessments were calculated: the first was a cumulative measure of the difference between the LMWH group and the control group, the second was a measure of the information available in the study. A plot of these two statistics was maintained: these values were the coordinates in the sequential design for the analysis. At each analysis, one point was drawn on the triangle shown in figure 1 and the global results for efficacy and safety were presented to the Data and Safety Monitoring Review Board. The pattern of all the points created was termed the sample path. When this path remained inside the triangle, the study had to be continued but if the sample path increased or decreased, the study had to be stopped. The sequential analyses were computed by PEST version 2.2. Other qualitative data were analysed by the chi-square test or Fisher's exact test, and the Student's $t$ test was used for quantitative data. All tests were two-tailed with a 5% level of significance. These analyses were performed on the statistical software SAS version 6.08.

## Results

From March 1993 to July 1994, 170 patients, 85 in each treatment group, having undergone THR under spinal anaesthesia, were included in the study and received at least one dose of the study medication. These patients were all considered in the safety analysis. Seven of the 170 patients were ongoing at the time of the decision to stop the inclusion recommended by the Data and Safety Monitoring Board. They were considered as overrunning patients and did not appear in the third sequential analysis ($n$=163). Among the 170 included patients, 17 patients (seven in the LMWH group and 10 in the control group) were not considered in the intent-to-treat analysis of efficacy, because venography could not be performed (12 patients: four in the LMWH group and eight in the control group) or because venography was found to be inadequate by the review committee (five patients: three in the LMWH group and two in the control group). Finally, a total of 153 patients were analysed on an intent-to-treat basis (78 in the LMWH group and 75 in the control group). The two treatment groups did not differ in baseline characteristics, excepted for gender (table 1). This factor, which was taken into account in the primary analysis of efficacy, was not found to affect the results of this analysis. The main characteristics of the surgical and anaesthetic procedure are presented in table 2.

### THROMBOEMBOLIC COMPLICATIONS

There were no deaths or clinical pulmonary emboli during the study. A total of 39 patients of the 153 evaluable patients (25.5%) presented with venogram-proved DVT of the lower extremities (table 3). Most were asymptomatic and only two

*Table 3* Incidence of venogram-proved DVT on day 10±2. $^{**}P<0.01$

| Thrombus site | LMWH ($n$=78) | Placebo ($n$=75) | Overall ($n$=153) |
|---|---|---|---|
| Proximal DVT | 2 | 12 | 14 |
| Distal DVT | 8 | 13 | 21 |
| Muscular VT | 1 | 3 | 4 |
| Total DVT$^{**}$ | 11 (14.1%) | 28 (37.3%) | 39 (25.5%) |

patients (one patient in each group) presented clinical signs of DVT which were confirmed by venography. Overall, the incidence of venous thrombosis on day 10±2 was 14.1% in the LMWH group (95% confidence interval 6–22%), compared with 37.3% (25–47%) in the control group. This difference was statistically significant ($P$=0.0016) for the triangular test corrected according to the 5% significance level adopted (table 3). None of the 17 excluded patients who did not undergo adequate venography were found to present with clinical signs suggesting DVT. No patient variable was found to affect overall comparison of efficacy outcome of the evaluable patients between the two treatment groups. Of the 39 DVT, eight were bilateral, 20 were in the operated legs and 11 were on the opposite side. Most were detected on systematic examination at day 10±2, whereas seven were detected by ultrasonography before the end of the treatment period (six in the control group and one in the LMWH group).

### BLEEDING COMPLICATIONS

No gross neurological sequelae were observed. Overall, major haemorrhage occurred in 1.2% and minor haemorrhages, including wound haematomas smaller than 1 cm, in 31.2% of patients (table 4). Two patients were considered to present with major haemorrhage: one patient in the LMWH group presented with postoperative haemorrhage at the surgical site on day 6, with a decrease in haemoglobin concentration of more than 4 g $dl^{-1}$, and requiring transfusion of 2 u. of packed red blood cells; and one patient in the control group presented with postoperative haemorrhage on day 3 through wound drainage with a decrease in haemoglobin concentration of more than 4 g $dl^{-1}$ and requiring transfusion of 2 u. of packed red blood cells, but no reintervention. Thirty-two patients in the LMWH group (37.6%) and 21 patients in the control group (24.7%) experienced minor haemorrhage ($P$=0.04). Haemorrhage did not lead to surgical reoperation or premature discontinuation of the study in any patient. There were no differences between the two groups in perioperative blood loss (table 4). Of the 170 patients, 23 received homologous transfusions (13.5%): 16 in the LMWH group and seven in the control group ($P$=0.044).

### OTHER ADVERSE EVENTS (FROM DAY 1 TO DAY 10±2)

There were no study withdrawals as a result of adverse events other than DVT or haemorrhages. A total of 45 patients with an unexpected adverse event were observed during the study: 24 patients in the LMWH group and 21 patients in the control group. The principal causes were subluxation of prosthesis in three patients requiring reintervention under general anaesthesia, symptomatic anaemia requiring transfusions in 11 cases, infection (wound infection or general infection) in 12 patients and other symptoms in 19 patients. Among the total number of unexpected adverse event, only five cases (three in the LMWH group and two in the control group) were considered as "possibly" or "probably" related to the study treatment. The remaining cases were considered as mild to moderate in intensity, and resolved within a few days even though the study treatment was maintained.

### 3-MONTH FOLLOW-UP PERIOD (FROM DAY 12 TO DAY 90)

A total of 169 patients (85 in the LMWH group and 84 in the control group) underwent post-surgical follow-up at 3 months (one patient was lost to follow-up). No deaths or thromboembolic events were observed during this period. Fourteen patients presented with further adverse events: six in the LMWH group and eight in the control group. The principal causes were subluxation of prosthesis after day 10 in four patients requiring reintervention under general anaesthesia, infection in two patients and other symptoms in eight patients.

### LABORATORY TESTS

There were no significant differences between the two groups in absolute and relative changes in red cells and haemoglobin concentration from day 0 to

*Table 4* Bleeding complications (mean (SD) or number)

| | LMWH | Placebo | $P$ |
|---|---|---|---|
| Spinal haematoma ($n$) | 0 | 0 | |

| >5 cm | 17 | 8 | |
| Total | 33 | 20 | 0.04 |
| Intraoperative blood loss (ml) | 395 (133.1) | 422 (122.9) | 0.65 |
| Postoperative blood loss (ml) | 783.4 (409.4) | 790.4 (381.7) | 0.90 |
| Global calculated blood loss (ml) | 1538 (928.9) | 1399.7 (928.9) | 0.40 |
| Transfusion rate (day 1 to day 12) | 18.8% | 8.2% | 0.044 |

day 10±2. No thrombocytopenia occurred in the postoperative period.

## Discussion

We have demonstrated that in patients undergoing THR under spinal anaesthesia, the use of LMWH prophylaxis associated with gradual compression stockings significantly decreased the incidence of DVT. The combination of spinal anaesthesia and gradual compression stockings alone, without LMWH, did not provide sufficient antithrombotic prophylaxis. No symptomatic pulmonary emboli were observed in either group.

Many clinical studies[4–7] and meta-analyses[8 9] have established that the use of LMWH is associated with an improved benefit/risk ratio compared with dextran,[16] unfractionated heparin[5–7] or oral anticoagulants[17] in orthopaedic surgery. Spinal or extradural anaesthesia has also been shown to decrease the incidence of postoperative DVT.[18–20] This effect can be explained by the vasodilatation induced by the pharmacological blocking of the sympathetic system resulting in increased venous blood flow in the lower extremities,[21] the effect of local anaesthetics[22 23] and subsequent haemodilution.[24] This has been confirmed recently in a review by Prins and Hirsh in fracture and elective hip surgery.[10] Despite a reduction in the incidence of postoperative DVT (without prophylaxis) of 46–55%, this effect remains controversial.

Another study in THR patients showed a much lower incidence of venogram-proved DVT (12%) after operation under extradural anaesthesia.[25] In patients with a fractured hip, a meta-analysis recently reported a risk reduction (odds ratio) for DVT four times lower with spinal anaesthesia in comparison with general anaesthesia,[26] and a prospective study in patients treated before and after operation with LMWH was unable to find any difference in the rate of DVT between patients operated on under general anaesthesia and those who underwent central neural block.[27] The antithrombotic effect is probably less than that reported initially by Modig and colleagues.[18 24 28] Our study represents one of the largest DVT prophylaxis studies in patients operated on under central neural block. Despite the use of central neural block, associated with gradual compression stockings, the incidence of DVT was 37.3% in the control group on day 10±2 after operation. A placebo group was considered to be justified because of the following reasons: all patients wore gradual compression stockings which, although insufficient in high-risk patients, have a proven antithrombotic effect[29–31]; patients were monitored closely by daily clinical examination, by Duplex scanning performed on day 3 and day 6, and by bilateral ascending venography performed on day 10±2; sequential analysis was performed after every 50 patients in order to assess blindly the DVT rate in both groups, so that the study could be interrupted as soon as a significant difference was noted between the two groups.

In our study, LMWH prophylaxis significantly reduced the rate of DVT to 14.1%, which is close to the generally reported incidence in such patients.[8 9] Although in Europe the dosage regimen of enoxaparin 40 mg s.c once daily, beginning before operation, is commonly approved for the prevention of postoperative DVT in THR patients,[6] a regimen beginning after operation was chosen in accordance with the recommendations issued by the consensus conference for thromboembolic diseases held in 1991.[13] The risk of extradural or subarachnoid haematoma induced by preoperative LMWH and central neural block is probably very low. Tryba estimated the risk for a spinal haematoma after central neural block to be 1:150 000 after extradural anaesthesia and 1:220 000 after spinal anaesthesia.[32] However, the severity of neurological consequences has to be considered carefully and case reports are still published. A recent literature search reported 61 cases of extradural or spinal haematoma involving central neural block.[12] Forty-two patients had a clotting disorder or were treated with anticoagulants without specification of dose. This incidence is probably underestimated because many of these cases are not reported. This study was not designed specifically to assess the risk of spinal haemorrhage with the combination of LMWH and central neural block, as specific neurological assessments were not performed and the study population was too small to demonstrate a valid difference in the incidence of spinal haematoma. Although no clinical symptoms suggesting a spinal haematoma were observed in our study, the use of extradural or spinal anaesthesia in patients receiving a preoperative dose of LMWH remains a concern.

The frequency of postoperative bleeding complications, including wound haematoma, is believed to increase in heparin-treated patients. This is the main reason for the reluctance of many surgical teams to use heparin prophylaxis. The results of this study confirmed this observation, although there was no difference between the two groups in the incidence of major haemorrhage. Patients in the LMWH group experienced significantly more wound haematomas than in the control group. However, there were no discontinuations of study treatment or surgical reinterventions related to haematoma in either group. The standard postoperative blood loss calculation[14] taking into consideration the perioperative period until day 3, showed no difference between the two groups. However, the global transfusion rate observed in this study appeared lower than that reported for THR surgery. This could be explained by the type of anaesthesia as noted in a recent meta-analysis.[33] When comparing the transfusion rate between the two groups, the observed difference was in favour of the control group, as expected.

In conclusion, spinal anaesthesia during THR surgery in association with gradual compression stockings alone was not sufficient to protect against the risk of postoperative DVT. The addition of LMWH beginning after operation reduced the risk of venogram-proved DVT and demonstrated an acceptable benefit/risk ratio compared with placebo.

## Acknowledgments

We are indebted to those who took part in the study: F. Clergue, MD, L. Dominici, MD (Hôpital Tenon, Paris); C. Pluvinage, MD, J. Preaut, MD, P. Brichard, MD (Polyclinique du Parc, Bar le duc); C. Blery, MD, A. Bacquet, MD (Centre Chirurgical St-Roch, Cavaillon); L.-J. Dupré, MD, M. Rouge, MD (Clinique du docteur Cléret, Chambéry); J. P. # Intrathecal infusion of bupivacaine with or without morphine for postoperative analgesia after hip and knee arthroplasty

M. BACHMANN, E. LAAKSO, L. NIEMI, P. H. ROSENBERG AND M. PITKÄNEN

## Summary

Postoperative pain after major orthopaedic operations can be controlled by continuous intrathecal administration of opioids or local anaesthetics. Effective intrathecal analgesia can be achieved through synergism of low doses of the two analgesic drugs and, possibly, less drug-related adverse effects. Therefore, we have evaluated the usefulness of a combined low-dose bupivacaine and morphine infusion in patients undergoing hip and knee arthroplasty. Spinal anaesthesia was induced in 55 ASA I–III patients with 0.5% bupivacaine 2 ml via a 28-gauge spinal catheter (L3–4 interspace) and 0.5-ml increments were given if needed. Intrathecal 24-h infusions consisted of bupivacaine 2 mg $h^{-1}$ alone ($n=18$), bupivacaine 1 mg $h^{-1}$ alone ($n=18$) or bupivacaine 1 mg $h^{-1}$ combined with morphine 8 μg $h^{-1}$ ($n=19$). The interview after 3, 6, 12 and 24 h included assessment of pain at rest and on movement (VAS scale), occurrence of sensory and motor block and nausea/vomiting. Bupivacaine 1 mg $h^{-1}$ combined with an infusion of morphine provided as good postoperative analgesia as bupivacaine 2 mg $h^{-1}$, but motor block disappeared earlier ($P=0.01$). Patients in the bupivacaine 1-mg $h^{-1}$ group required more supplementary doses of oxycodone i.m. than the other groups ($P=0.04$). Time to first oxycodone dose from the start of intrathecal infusion did not differ between groups. The frequency of nausea and vomiting was similar in all groups. In spite of this, antiemetic medication was required more often in the bupivacaine 1-mg $h^{-1}$ group (possible because of opioid rescue medication). On the ward, one patient in the bupivacaine 2-mg $h^{-1}$ group experienced a new increase in sensory block with concomitant hypotension. One patient in the same group had minor decubitus on the heel of the operated leg, probably because of prolonged motor block. We conclude that intrathecal infusion of a combination of bupivacaine 1 mg $h^{-1}$ and morphine 8 μg $h^{-1}$ produced adequate postoperative analgesia. Unfortunately, postoperative nausea and vomiting was a frequent disturbing adverse effect. (*Br. J. Anaesth.* 1997; **78**: 666–670).

**Key words**
Anaesthetic techniques, subarachnoid. Pain, postoperative. Anaesthetics local, bupivacaine. Analgesics opioid, morphine. Surgery, orthopaedic.

Continuous spinal anaesthesia and analgesia have been achieved effectively by administration of local anaesthetics for surgery and opioids for postoperative pain.[1–4] Opioids are generally given intrathecally for analgesia[3 5] either as a single bolus[3 5 6] or as a continuous infusion.[2 5] Treatment of postoperative nausea and vomiting (PONV) after intrathecal opioids has not yet been mastered.[7 8]

Recently, the usefulness of continuous administration of intrathecal bupivacaine for postoperative analgesia has been evaluated.[4 9] We showed that continuous infusion of bupivacaine 2 mg $h^{-1}$ produced adequate analgesia after hip and knee arthroplasty but the reappearance of spinal block and concomitant haemodynamic instability in some patients suggested that it was risky in terms of the benefits of this analgesia regimen.[4]

The synergism between local anaesthetics and opioids in extradural analgesia is a well established phenomenon.[10] This effect may be useful also in continuous intrathecal analgesia and thus the occurrence of adverse effects of both components should be reduced. Therefore, we have combined 0.25% bupivacaine and 0.002% morphine for low-dose continuous intrathecal infusion and evaluated its efficacy in the control of postoperative pain in comparison with infusion of bupivacaine alone.

## Patients and methods

The study was approved by the Ethics Committee of the hospital and informed consent was obtained from each patient. We studied 60 ASA I–III patients, aged 44–89 yr, undergoing elective hip or knee arthroplasty.

On the day of surgery, oral diazepam 5–15 mg was given as premedication. Subarachnoid puncture was performed in the midline at the L3–4 interspace, with the patient in the lateral position. A 28-gauge spinal catheter (CoSPAN Kendall, Basingstoke, UK) was inserted via a 22-gauge spinal needle. The catheters were advanced 3 cm past the needle tip into the subarachnoid space. Plain 0.5% bupivacaine 2 ml was injected via the catheter for induction of

spinal anaesthesia. Patients undergoing knee arthroplasty were turned gently to the supine horizontal position and patients undergoing hip arthroplasty remained in the lateral recumbent position. Cephalad spread of analgesia was assessed by pinprick. After a period of 15 min, incremental doses of bupivacaine 0.5 ml were administered when necessary with the aim of reaching a spinal block level of T10.

A double-blind study design was used with patients allocated randomly to one of three groups, each comprising 20 patients. Patients received a coded solution for spinal infusion containing plain 0.5% bupivacaine 0.4 ml $h^{-1}$ (2 mg $h^{-1}$), plain 0.25% bupivacaine 0.4 ml $h^{-1}$ (1 mg $h^{-1}$) or 0.25% bupivacaine combined with morphine 20 μg $ml^{-1}$ (192 μg of morphine in 24 h). The infusion (JMS Syringe pump SP-100, JMS Company, Ltd, Hirosima, Japan) was started 60 min after induction of spinal anaesthesia if the level of spinal block was below T6. If not, the infusion was started after the sensory analgesia level had decreased below T6 and haemodynamic variables were stable. All patients had a urinary catheter during the study.

During operation, small doses of sedatives or fentanyl were given as required. I.v. fluids, including packed red cells, were given according to the clinical requirements of each patient. Arterial pressure and heart rate were recorded at 5-min intervals during surgery and at 10-min intervals in the post-anaesthesia care unit. ECG and peripheral oxygen saturation were monitored continuously. Patients were transferred to the ward 3–5 h after surgery when they were haemodynamically stable (changes in heart rate or arterial pressure ±15% compared with preoperative values).

For postoperative pain, paracetamol 1 g was given three times a day. If adequate analgesia was not achieved (at the operation site) oxycodone 0.14 mg $kg^{-1}$ i.m. was administered at request. Metoclopramide 10 mg i.v. was given for PONV when needed. Patients were interviewed by one of the investigators 3, 6, 12 and 24 h after the intrathecal infusion was started. Each interview included an assessment of the intensity of pain at rest and on movement of the operated leg using a visual analogue scale (VAS) (0–10). Cephalad extension of analgesia was assessed by pinprick and the degree of motor block (scale 0–3, 0=no block, 3=complete motor block) of the lower extremities was recorded using the criteria described by Bromage.[11] Heart rate, arterial pressure and the occurrence of nausea and vomiting were also recorded.

The spinal catheters were removed by one of the investigators on the first postoperative day. For removal, the patient was placed in the same flexed recumbent position as during the puncture.

### STATISTICAL ANALYSIS

Statistical analysis of patient data and single efficacy end-points (VAS values) was performed using one-way analysis of variance; Bonferroni corrections were used in pairwise comparisons. Frequency data were compared using the chi-square test. Motor and sensory block and doses of analgesics and antiemetic drugs needed were analysed with non-parametric Kruskal–Wallis one-way analysis of variance using the Bonferroni-corrected Mann–Whitney test for pairwise comparisons. $P<0.05$ was considered statistically significant.

## Results

The study was discontinued in five patients; two were excluded because of accidental disconnection of the hub of the catheter and one patient in the bupivacaine 2-mg $h^{-1}$ group and one patient in the bupivacaine–morphine group wanted the infusion interrupted because of disturbing reappearance of sensory (T6 and T9 dermatomes, respectively) and motor block. The patient in the bupivacaine

2-mg h$^{-1}$ group also developed transient hypotension 10 h after surgery and required extra i.v. infusion of Ringer's acetate. One patient had an acute myocardial infarction and was therefore excluded from the study.

Data from the remaining 55 patients were analysed. Patient groups were comparable in age, weight, height, sex, arterial pressure and heart rate values obtained before operation, and type of surgery (table 1). Similarly, there were no differences in median cephalad dermatome level of sensory block 60 min after induction of spinal anaesthesia. Doses of sedatives, amount of intraoperative fluids and blood products did not differ between groups.

We found that 78% (14/18) of patients in the bupivacaine 1-mg h$^{-1}$ group needed supplementary opioid medication compared with 39% and 31% in the two other groups ($P=0.01$) during the 24-h postoperative period (table 2).

The number of supplementary oxycodone doses differed between groups ($P=0.04$), being higher in the bupivacaine 1-mg h$^{-1}$ group than in the other groups (table 2). Mean time from induction of anaesthesia to administration of i.m. opioid was comparable in all groups. VAS scores at 3, 6, 12 and 24 h at rest and on movement did not differ between groups. VAS scores were relatively low also during movement (table 3), and as a rule patients reported higher pain scores on movement than at rest (ns). At 24 h, patients who received either bupivacaine 1 mg h$^{-1}$ or bupivacaine–morphine experienced significantly more pain on movement of the operated leg than at rest compared with patients in the bupivacaine 2-mg h$^{-1}$ group ($P=0.03$) (table 3).

During the 24-h postoperative follow-up period, extension of sensory analgesia level and the intensity of motor block decreased in all groups. However, compared with the other groups, the bupivacaine 2-mg h$^{-1}$ group had significantly more extensive sensory block at 12 h ($P=0.02$) and at 24 h ($P=0.05$) than the other groups (table 3). Motor block was comparable in all groups at 3, 6 and 12 h. At 24 h after the start of infusion, partial motor block was observed in the bupivacaine 2-mg h$^{-1}$ group, and no motor block in the two other groups ($P=0.01$) (table 3).

On the ward all patients in the bupivacaine 2-mg h$^{-1}$ group, except the one mentioned above, were haemodynamically stable. There was no difference in the incidence of PONV between groups. Patients in the bupivacaine 1-mg h$^{-1}$ group were given more antiemetics than patients in the two other groups ($P=0.02$) (table 4). One patient in the bupivacaine 2-mg h$^{-1}$ group developed a minor decubitus on the heel of the operated extremity during the first week after surgery. This patient had second degree motor block 24 h after surgery, that is until the end of the intrathecal infusion. The skin healed with conservative therapy.

## Discussion

Our data indicated that continuous low-dose infusion of morphine 8 $\mu$g h$^{-1}$ combined with continuous infusion of bupivacaine 1 mg h$^{-1}$ provided as good postoperative analgesia as bupivacaine 2 mg h$^{-1}$ without opioid. This analgesic effect, as measured by requirements for supplementary opioids, was significantly better than the effect of bupivacaine 1 mg h$^{-1}$ alone. In addition to analgesia via spinal cord opioid receptors, intrathecal morphine suppresses selectively ascending A-delta and C-fibre activity evoked by stimulation of primary nociceptive afferents.[12] In animal models it has been shown that spinally administered morphine potentiates the analgesic effects of bupivacaine.[13] This concept has been used successfully in extradural analgesia for many years.[14,15] It is suggested that bupivacaine induces conformational change in the spinal opioid receptor thus facilitating synergism.[13] This synergistic effect has been demonstrated previously using single bolus doses in the clinical setting.[16]

In addition to good analgesia, the bupivacaine–morphine combination caused less motor block than the higher dose of bupivacaine alone. This might be clinically important even in patients who are not allowed to move in the first 24 h after surgery, because patients are encouraged to exercise their legs as early as possible in order to maintain good perfusion of the extremities, even during bed rest. The bed sore on the heel of one of our patient may be blamed on postoperative analgesia. Therefore, when higher doses of continuous intrathecal local anaesthetics are used it is important that the patient's position must be changed during the postoperative period if they are not able to move their legs voluntarily.

The use of spinal morphine, especially in higher doses, is associated with adverse effects such as respiratory depression, urinary retention, pruritus, and nausea and vomiting.[17] Higher peak concentrations of opioids observed after single boluses may increase the incidence and severity of side effects.[18] In our study we did not notice any difference in the incidence of nausea and vomiting between the groups, perhaps because the dose of morphine was relatively small. Interestingly, requirements for antiemetic medication were highest in the bupivacaine 1-mg h$^{-1}$ group. One explanation might be that patients in this group needed more systemically administered supplementary opioids which possibly induced greater intensity of nausea and therefore a greater demand for antiemetics.

Intrathecally administered plain bupivacaine is unpredictable regarding the final cephalad spread of the block.[19] In our study only one patient (in the bupivacaine 2-mg h$^{-1}$ group) suffered transient hypotension on the ward. This was related to the reappearance of the spinal block to T6. Also, in our previous study with intrathecal infusion of plain bupivacaine, reappearance of spinal block occurred relatively late during the first postoperative day.[4] Previously we have demonstrated changes in the level of bupivacaine spinal anaesthesia by changing the patient's posture 80–115 min after induction of anaesthesia.[20] Such a sudden change is probably caused by bulk displacement of CSF and movement of local anaesthetic which has not yet been bound or absorbed. On the other hand, the slowly progressing extension of the block on the ward, with patients in the horizontal position, resembles the slower diffusional type of drug distribution.

Regional anaesthetic and analgesic techniques are becoming popular for postoperative analgesia.[21] Extradural opioids are frequently combined with local anaesthetics for postoperative extradural analgesia because of their synergistic effects. For instance, combinations of morphine and bupivacaine,[22] fentanyl and bupivacaine[23] or sufentanil and bupivacaine[24] for extradural postoperative analgesia have been found to be superior to bupivacaine alone. Most importantly, the synergistic combination of an opioid and bupivacaine appears to be effective for pain during movement.[22] Also, in this study enhanced intrathecal analgesia tended to be more pronounced with movement but was also present at rest.

It should be emphasized that the intensity of pain experienced by our patients remained low also at movement and therefore the tests we used may not be sensitive enough to detect a significant additive or synergistic analgesic effect of drug combinations.[25]

Continuous spinal anaesthesia with local anaesthetics produces profound intraoperative analgesia and motor block and the duration of analgesia can be adjusted to the duration of surgery. In spite of technical problems,[8,26] when a spinal microcatheter has been placed for intraoperative analgesia, it may be used after operation also. We have demonstrated that the combination of a low dose of morphine (8 $\mu$g h$^{-1}$) and bupivacaine (1 mg h$^{-1}$) produced as good postoperative analgesia as twice the dose (2 mg h$^{-1}$) of bupivacaine alone, but with less motor block.

# Hyaluronidase and peribulbar block

G. A DEMPSEY, P. J. BARRETT AND I. J. KIRBY

## Summary

We have assessed the effect of two concentrations of hyaluronidase on the quality of peribulbar block, using a low volume, single injection technique. We studied 200 patients undergoing elective intraocular surgery, allocated randomly to one of three groups. Group 1 (*n*=50) received peribulbar block with 5 ml of a 1:1 mixture of 0.5% plain bupivacaine and 2% plain lignocaine. Group 2 (*n*=75) received this solution supplemented with hyaluronidase 50 iu ml$^{-1}$. Group 3 (*n*=75) received the same solution supplemented with hyaluronidase 300 iu ml$^{-1}$. Lack of ocular motility was considered to be the only objective sign of successful block and movement of each rectus muscle was scored at 1-, 5- and 10-min intervals. If the block was successful at 5 min, the 10-min score was omitted. If the block was unsuccessful at 5 min, a second injection of 2% lignocaine 3 ml was given and additional assessments performed at 5-min intervals. At 1 min, ocular motility scores were significantly lower in group 3 compared with the control group ($P<0.05$). The incidence of satisfactory block at 5 min was increased in both groups given hyaluronidase (group 2, $P<0.05$; group 3, $P<0.001$). There were no significant differences between groups 2 and 3 with respect to quality of block at 5 min. Hyaluronidase in both concentrations improved the quality of peribulbar block at 5 min, and when used in a concentration of 300 iu ml$^{-1}$, also improved the speed of onset of block. (*Br. J. Anaesth.* 1997; **78**: 671–674).

**Key words**
Anaesthetic techniques, regional, peribulbar. Surgery, ophthalmic Enzymes, hyaluronidase.

Peribulbar block provides good quality local anaesthesia for intraocular surgery, combining low morbidity with high efficacy.[1] Hyaluronidase is thought to promote the spread of local anaesthetic solutions by hydrolysing glycosidic bonds within the hyaluronic acid which forms the interstitial barrier.[2] Its efficacy has been proved when used for retrobulbar block.[3 4] However, its advantage in peribulbar block is less clear, with some studies claiming no beneficial effect[5 6] and others reporting improved quality of block.[7 8] Those studies claiming no beneficial effect have used varying concentrations of hyaluronidase, up to 150 iu ml$^{-1}$, and studied relatively few patients. More recently, pH-adjusted solutions containing hyaluronidase have been used to some effect.[9]

We postulated that the uncertainty relating to the effect of hyaluronidase on peribulbar block may result in part from insufficient numbers of patients studied and also from the use of inadequate concentrations. Therefore, we have performed a large, randomized, controlled study to assess the effect of two concentrations of hyaluronidase on the quality of peribulbar block.

## Patients and methods

After approval from the local Ethics Committee and informed consent, we studied 200 unpremedicated patients, ASA I, II or III, undergoing elective intraocular surgery under local anaesthesia. Patients were allocated randomly to one of three groups: group 1 (*n*=50) received peribulbar block with 5 ml of a 1:1 mixture of 0.5% plain bupivacaine and 2% plain lignocaine; this group served as a control. Group 2 (*n*=75) received the same volume of solution supplemented with hyaluronidase 50 iu ml$^{-1}$. Group 3 (*n*=75) received the same solution supplemented with hyaluronidase 300 iu ml$^{-1}$.

Before the block, a vein was cannulated and monitoring of heart rate, oxygen saturation and non-invasive arterial pressure was commenced in all patients. Topical anaesthesia to the infraorbital skin was provided by EMLA cream applied at least 1 h before surgery, and to the conjunctiva by 0.4% oxybuprocaine drops applied immediately before performing the block.

All blocks were performed by the same investigator using a low volume (5 ml), single transcutaneous inferolateral injection technique, and a standard 25-mm, 23-gauge needle, as described by Apel and Woodward.[10] With the gaze fixed straight ahead in the primary position, the injection site was identified at the junction of the lateral one-third and medial two-thirds of the inferior orbital rim. The direction of needle insertion was slightly medial and cephalad, with the tip of the needle being elevated towards the end of injection. Immediately after injection, a McIntyre weight (mercury-filled bag)

was applied to the closed eye to promote spread of local anaesthetic and softening of the globe. Reduction of ocular motility was considered to be the only reliably reproducible sign of successful block; movement of the superior, inferior, medial and lateral recti were scored by an observer blinded to the solution used, in a manner similar to that described by Nicoll and colleagues.[4]

Movements were scored as: normal=2, reduced=1 and akinesia=0, giving a maximum aggregate score for the four muscles of 8. Ocular motility was assessed at 1-, 5- and 10-min intervals and a score of 4 or less, from reduced movements in all directions, was taken to indicate successful block. If a successful block was achieved at 5 min, the 10-min score was omitted. If however, the block was unsuccessful at 5 min, supplementary injection of 2% plain lignocaine 3 ml was administered, in the manner described earlier, with additional assessments performed at 5-min intervals. The total volume of local anaesthetic required to produce successful block was recorded. Increased intraocular pressure was assessed by experienced palpation only: it was noted whether or not the eye felt tense.

### STATISTICAL ANALYSIS

Patient data were analysed using analysis of variance (ANOVA), while ocular motility scores and total volume of local anaesthetic required were compared using chi-square tests. Clinical detection of increased intraocular pressure in the three groups was compared using Fisher's exact test.

## Results

There were no significant differences between the three groups in age, sex or ASA status (table 1).

Ocular motility scores at 1 min for group 3 were significantly lower than control values (group 1), with 39 (52%) patients achieving a score of $\leqslant 4$. There were no significant differences at 1 min between groups 1 and 2 or groups 2 and 3 (table 2).

| Group 3 | |
| H 300 iu ml$^{-1}$ ($n$=75) | 30 (40)*** |

At 5 min, the incidence of successful blocks was significantly greater in both group 2 ($P<0.05$) and group 3 ($P<0.001$) compared with the control. There were no significant differences between groups 2 and 3 at this time for both achieving an ocular motility score of $\leqslant 4$ (table 3) and achieving complete akinesia (table 4).

By 5 min, 164 patients from the three groups had achieved successful block and were not assessed further. Of the remaining 36 patients, 34 had achieved successful block by 10 min after a second injection. All but two of the 200 patients had achieved successful block by 10 min; both of these patients were from group 3 and required a third injection (total volume of local anaesthetic 11 ml) to achieve successful block. No patient proceeding to surgery experienced any intraoperative discomfort.

Four patients in group 1 had clinical evidence on palpation of a sustained increase in intraocular pressure (IOP). In one case this necessitated cancellation of surgery. In another patient, i.v. acetazolamide was required and in the two other patients, ocular compression for 20 min before surgery was necessary. None of the four patients noted to have a "tense" eye on palpation had received a volume of injectate greater than 5 ml, as all had achieved ocular motility scores of 4 or less by 5 min.

The two patients with the most marked increases

*Table 5* Numbers (%) of patients with clinical evidence of increased intraocular pressure (IOP). $^{***}P<0.001$ compared with control (Fisher's exact test). H=Hyaluronidase

| | IOP satisfactory | "Tense" eye |
|---|---|---|
| Group 1 | | |
| Control ($n$=50) | 46 (92) | 4 (8) |
| Group 2 | | |
| H 50 iu ml$^{-1}$ ($n$=75) | 75 (100)*** | 0 (0) |
| Group 3 | | |
| H 300 iu ml$^{-1}$ ($n$=75) | 75 (100)*** | 0 (0) |

in IOP were brought to our attention by the ophthalmic surgeon who was unaware of the local anaesthetic solution used. The remaining two patients were noted to have "tense" eyes by one of the authors, who may have been aware of the solution used. Comparison of the number of patients in each group with a tense eye, using Fisher's exact test, showed a highly significant difference ($P<0.001$) between the three groups (table 5).

As the risks involved in undertaking intraocular surgery in patients with a high IOP are significant, we felt that we were no longer justified in recruiting to group 1 and only 50 patients were studied.

## Discussion

We have demonstrated a beneficial effect of hyaluronidase 300 iu ml$^{-1}$ combined with 0.5% bupivacaine and 2% lignocaine in improving the speed of onset of peribulbar block compared with local anaesthetic solutions alone. Hyaluronidase in concentrations of 300 iu ml$^{-1}$ and 50 iu ml$^{-1}$ also improved the quality of peribulbar block at 5 min compared with control, reducing the need for supplementary injection. We were unable to show any significant difference between the two concentrations of hyaluronidase with respect to quality of block at 5 min.

A study by Roberts, Macleod and Hollands suggested that the beneficial effects of hyaluronidase appeared only when local anaesthetic solutions were alkalinized to allow improved enzymatic action.[9] Our findings do not concur with these results in that we found hyaluronidase to be effective in improving the quality of block without pH adjustment. This may partly result from the different concentrations of hyaluronidase used in the two studies (10 iu ml$^{-1}$ *vs* 50/300 iu ml$^{-1}$), differences in technique (two injection peribulbar technique *vs* single injection peribulbar block) and time of assessment (only at 30 min compared with 1, 5 and 10 min in our study). There were also differences in study design with the former using five different groups and studying only 100 patients.

In addition, our own observations showed that the use of hyaluronidase itself may alter the pH of a local anaesthetic because of the presence of phosphate buffers within the preparation, so that a 1:1 mixture of 0.5% plain bupivacaine and 2% plain lignocaine has a pH of 4.9, the same solution with hyaluronidase 50 iu ml$^{-1}$ has a pH of 5.0, while a solution with hyaluronidase 300 iu ml$^{-1}$ has a pH of 5.6. It is well recognized that local anaesthetics exist in both the uncharged and charged cationic forms within the body and that the ratio between the two varies with the pH of the surrounding tissues. It is believed that local anaesthetic molecules penetrate nerve membranes more rapidly in their uncharged form,[11] with the ionized form being the active structure.[12] For both lignocaine and bupivacaine, as pH decreases, there is an increase in the cationic form. Conversely, as pH increases, more of the drug exists in the free base form, allowing the drug to penetrate the nerve fibre more rapidly. Several authors have found alkalinizing local anaesthetic solutions to be effective for both peribulbar block[13] and other blocks.[14] It may be that the efficacy of hyaluronidase in improving onset of block is at least partly a result of its ability to increase the pH of local anaesthetic solutions.

It has also been postulated that because of its effects on absorption, hyaluronidase may lead to higher plasma concentrations of local anaesthetic and reduce the duration of action of block.[15] A recent study showed that addition of hyaluronidase to local anaesthetic solutions hastened the absorption of both lignocaine and bupivacaine but did not increase the maximum plasma concentration achieved.[16] Although we did not measure plasma concentrations of local anaesthetic, toxicity with this technique would not be expected because of the small amount of drug used. Duration of nerve block was sufficient to complete surgery in all patients.

Of additional interest in this study was the sustained increase in IOP in four patients in the control group, which occurred despite the use of a low volume of injectate (5 ml). We felt that this was so significant that we could no longer justify further recruitment to this group. There is only one previous report which suggested an association between peribulbar block without hyaluronidase and sustained increases in IOP.[17] The underlying aetiology may be related to incomplete dispersal of local anaesthetic solution within the periocular compartment. However, all patients who had increases in IOP appeared clinically to have small orbits with short axial lengths (all ≤22 mm). This observation may warrant further investigation.

Each time a needle is introduced into the orbit, there is a small but definite risk of complication. Successful block from a single injection is therefore desirable. Our study has shown that this is most likely to be achieved when hyaluronidase is added to the solution. Because of its beneficial effects on speed of onset, ease of administration and lack of significant toxicity or adverse effect on local anaesthetic absorption, we would advocate the use of hyaluronidase in a concentration of 300 iu ml$^{-1}$.

# Intraperitoneal lignocaine for pain relief after total abdominal hysterectomy

K. M. WILLIAMSON, B. R. COTTON AND G. SMITH

## Summary

In this preliminary randomized study, we have measured pain scores at rest and on movement, 24 and 48 h after operation in 19 control patients, who received 50 ml of saline i.p., and in 20 test patients, in whom 50 ml of saline solution containing lignocaine 200 mg and adrenaline 1:500 000 were instilled into the peritoneal cavity after total abdominal hysterectomy. We found that there was no difference in linear analogue scores for nausea, pain on movement or morphine consumption after operation between the two groups, but pain scores at rest were significantly lower in the lignocaine group at 24 and 48 h compared with the saline group. In the lignocaine group, blood sampling over a 3-h period revealed a mean maximum serum concentration of 0.4 $\mu$g ml$^{-1}$ at 3 h and a highest concentration in any patient of 0.87 $\mu$g ml$^{-1}$. (*Br J. Anaesth.* 1997; **78**: 675–677).

**Key words**
Surgery, gynaecological. Anaesthetics local, lignocaine. Pain, postoperative.

Recently, there has been interest in the instillation of local anaesthetic solutions into the peritoneal cavity for treatment of pain after abdominal surgery. This technique has been described as producing effective analgesia after laparoscopic cholecystectomy by some workers[1–2] but not by others.[3] After gynaecological laparoscopy, there is stronger evidence for effective analgesia.[4–7] Serum concentrations of local anaesthetics have been measured after i.p. administration of lignocaine and bupivacaine during gynaecological laparoscopy and the authors concluded that the use of a plain solution of lignocaine led to relatively high but safe serum concentrations of the drug with a dose of 400 mg. The addition of adrenaline was shown to produce a substantial reduction in the maximum serum concentrations attained.[8]

We were interested to see if i.p. instillation of local anaesthetic produced effective analgesia after total abdominal hysterectomy. Because of the greater degree of trauma after hysterectomy than after laparoscopy, we were concerned that the rate of absorption of local anaesthetic might be faster after hysterectomy. Consequently, we devised a study to assess serum concentrations of lignocaine after instillation of a relatively small dose (200 mg) of lignocaine into the peritoneal cavity and, at the same time, examine the effect on postoperative analgesia to serve as a guide to a subsequent study designed to assess the analgesic efficacy of larger doses of local anaesthetic solutions.

## Patients and methods

After obtaining approval from the Leicestershire Ethics Committee and written informed patient consent, we studied 40 patients undergoing total abdominal hysterectomy. All patients were aged 20–60 yr, ASA grade I or II, not undergoing surgery for malignancy and were scheduled for surgery undertaken via a standard Pfannenstiel incision. Patients were excluded if they had cardiac or vascular disease, hepatic disease, allergy to local anaesthetic agents or any contraindications to local anaesthesia.

Anaesthesia was standardized and comprised premedication with temazepam 10 mg, induction with propofol 150–200 mg, intubation of the trachea and controlled ventilation of the lungs using 1.5–2.0% enflurane and 66% nitrous oxide in oxygen. Vecuronium was given as required to produce neuromuscular block and a standard dose of morphine 10 mg (combined with prochlorperazine 12.5 mg) was given shortly after induction of anaesthesia to provide analgesia in the immediate postoperative period. After induction of anaesthesia, a second cannula was inserted into the contralateral antecubital fossa from the arm in which the i.v. infusion was sited and 10-ml samples of venous blood were obtained before and at 1, 3, 5, 10, 15, 20, 30, 60, 120 and 180 min after instillation of local anaesthetic into the peritoneal cavity. After administration of morphine, patients were allocated randomly using sealed envelopes and random numbers generated by computer to receive either local anaesthetic solution or an equal volume of saline solution. The local anaesthetic solution comprised 50 ml of 0.4% lignocaine with adrenaline (1:500 000 dilution) prepared by adding 30 ml of saline to 20 ml of 1% lignocaine containing adrenaline 1:200 000.

K. M. WILLIAMSON, MRCOG, FRCS, Department of Obstetrics and Gynaecology, City Hospital, Hucknall Road, Nottingham NG5 1PB. B. R. COTTON, FRCA, G. SMITH, BSC, MD, FRCA, Department of Anaesthesia, Leicester Royal Infirmary, Leicester LE1 5WW. Accepted for publication: January 6, 1997.

Total abdominal hysterectomy was carried out using a standard technique by one of four surgeons, the majority being performed by a single surgeon. The peritoneum over the vault of the vagina was not closed and the local anaesthetic or saline solution was instilled into the pelvic cavity only after haemostasis had been secured, all packs removed from the peritoneal cavity and the patient placed in the supine horizontal position.

After operation, patients were provided with patient-controlled analgesia equipment (Abbott PCA II; morphine 1-mg boluses with 8-min lock-out), the use of which had been explained in detail at the preoperative assessment. This technique is used routinely and supervised by the sister in the acute pain service at Leicester Royal Infirmary. The patient and pain sister, who acted as an observer, the recovery room staff, surgical staff and the nursing staff on the ward were blinded to the nature of the solution administered into the peritoneal cavity. In our hospital, the pain sister is allowed to give bolus doses of morphine up to 5 mg i.v. in the recovery room in order to provide optimal analgesia immediately after recovery.

In the postoperative period, the patient completed linear analogue pain scores, at 24 and 48 h, for pain at rest and during a standardized movement (sitting upright from the supine horizontal position). In addition, she completed linear analogue scores for nausea and sedation.[8]

Serum concentrations of lignocaine were measured using high pressure liquid chromatography and ultraviolet detection. The intra-assay coefficient of variation was 3.6% and the inter-assay coefficient of variation was 4.2%. The limit of detection was 0.04 μg $ml^{-1}$.

Data were analysed using SPSS version 6.0 for Windows running on an IBM compatible PC and serum concentrations of lignocaine were plotted using Graphpad Prism version 2.0. Data were subjected first to Komolgorov–Smirnov goodness of fit tests for normality of distribution. All data were found to be distributed normally and were therefore compared using the Student's *t* test. $P<0.05$ was taken as significant. Because of concern about the normality of distribution of linear analogue scores, data were analysed also by Mann–Whitney *U* tests.

## Results

Data from one patient in the saline group were rejected because of failure of standardization of the anaesthetic technique. Thus we have compared data from 19 patients in the saline group with 20 in the lignocaine group. The two groups were comparable in age and duration of anaesthesia (table 1). Cumulative morphine consumption (total given in the intraoperative period, in the recovery room and by PCA) in the first 24 and 48 h was the same in both groups and the mean number of injections of prochlorperazine to control vomiting was the same also in both groups. There was no difference between the two groups in the bolus dose of morphine given by the pain sister in the recovery room. In the saline group, there was a total of 11 episodes of vomiting (number of individual retchings or vomits) in seven patients and in the lignocaine group a total of nine episodes of vomiting in six patients, all within the first 24 h.

*Table 1* Patient characteristics and postoperative data (mean (SEM) or range)

| | Saline ($n$=19) | Significance | Lignocaine ($n$=20) |
|---|---|---|---|
| Age (yr) | 43.2 (30–58) | ns | 39.6 (28–59) |
| Weight (kg) | 63.8 (2.3) | ns | 63.1 (1.9) |
| Duration of anaesthesia (min) | 60.2 (2.9) | ns | 55.5 (2.7) |
| Morphine consumption (mg) | | | |
| 0–24 h | 59.8 (3.6) | ns | 59.5 (4.3) |
| 0–48 h | 89.4 (5.4) | ns | 75.8 (6.9) |
| Dose of prochlorperazine (mg) | | | |
| 0–24 h | 11.3 (2.3) | ns | 15.6 (2.9) |
| Episodes of vomiting | | | |
| 0–24 h | 11 ($n$=7) | ns | 9 ($n$=6) |
| 24–48 h | 0 | | 0 |
| Pain scores (mm) | | | |
| At 24 h rest | 39.4 (4.7) | <0.05 | 26.0 (4.1) |
| At 24 h movement | 47 0 (6.0) | ns | 42.0 (4.6) |
| At 48 h rest | 23.2 (3.9) | <0.05 | 11.5 (2.7) |
| At 48 h movement | 33.6 (4.1) | ns | 23 5 (3.6) |

After operation, there was a small but significant difference in linear analogue pain scores both at 24 and 48 h for patients at rest; the lignocaine group reported significantly less pain than the saline group ($P<0.05$ using Student's *t* tests and also the Mann–Whitney *U* test). Although there was also less pain reported on movement in the lignocaine group, this was not significantly different from that in the saline group. There were no significant differences between the two groups in linear analogue scores for nausea or sedation (data not shown).

Lignocaine was absorbed rapidly from the peritoneal cavity; serum concentrations reached a plateau by approximately 5 min after instillation into the pelvic cavity. Thereafter, plasma lignocaine concentration tended to increase very slowly and to a very slight extent for the duration of sampling over 3 h (fig. 1). The final mean maximum concentration achieved at 3 h was approximately 0.4 μg $ml^{-1}$. The highest concentration observed at any time in any patient was 0.87 μg $ml^{-1}$.

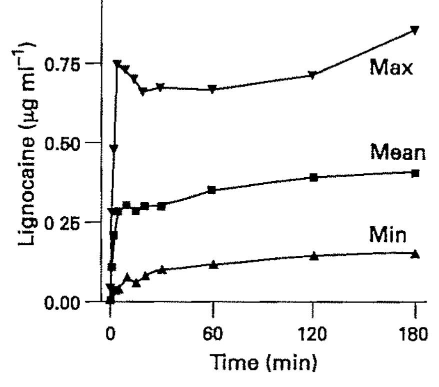

*Figure 1* Serum concentrations of lignocaine after instillation of a dose of 200 mg with adrenaline 1:500 000 into the pelvic cavity after hysterectomy. Data shown as mean values with minima and maxima ($n$=20).

## Discussion

We have found that instillation of a relatively small dose of lignocaine (200 mg) into the pelvic cavity before closure of a Pfannenstiel incision after total abdominal hysterectomy was associated with lower pain scores at rest, at 24 h and at 48 h after operation compared with a control group given saline; however, only data for pain at rest were statistically significant. In every other respect, the two groups of patients behaved in a similar manner, with the same degree of postoperative emesis, same requirements for antiemetics and similar consumptions of morphine by PCA over the 48-h period after operation. There was no morbidity associated with instillation of solutions into the peritoneal cavity and there was no morbidity or mortality in the patients examined in this study.

We found that lignocaine was absorbed relatively rapidly from the peritoneal cavity reaching approximately 0.25 $\mu$g ml$^{-1}$ by 5 min, but subsequently there was a slow gradual increase up to approximately 0.4 $\mu$g ml$^{-1}$ by 3 h after instillation.

Narchi and colleagues [8] found that, after gynaecological laparoscopy, the rate of absorption of lignocaine from the peritoneal cavity was relatively slow; the time to maximum concentration ($tC_P$max) was reached at 29 min with plain lignocaine 400 mg, at 58 min using lignocaine 400 mg with adrenaline 1:320 000 and at 72 min with lignocaine 400 mg and adrenaline 1:800 000. In both Narchi's study and ours, the maximum concentration of lignocaine attained ($C_P$max) was relatively low. Narchi and colleagues found a $C_P$max value of 4.3 $\mu$g ml$^{-1}$ with plain lignocaine 400 mg, 2.3 $\mu$g ml$^{-1}$ with lignocaine 400 mg and adrenaline 1:320 000, and 1.89 $\mu$g ml$^{-1}$ using lignocaine 400 mg with adrenaline 1:800 000.

We used half the dose of lignocaine that Narchi and colleagues used. Our data suggest that if we had used lignocaine 400 mg with adrenaline, we would have found a $C_P$max value of 0.8 $\mu$g ml$^{-1}$ which is one-third of the $C_P$max found in that study; this suggests that the rate of absorption of lignocaine was slower after hysterectomy than after gynaecological laparoscopy.

The serum concentration of lignocaine at which toxic symptoms begin to occur is approximately 3 $\mu$g ml$^{-1}$ in the unmedicated subject but the threshold increases in patients during anaesthesia.[9] Thus our data suggest that a dose of lignocaine 400 mg would be extremely unlikely to result in toxicity when given into the pelvic cavity after abdominal hysterectomy.

In summary, we have found that administration of lignocaine 200 mg into the peritoneal cavity after total abdominal hysterectomy was associated with low serum concentrations of lignocaine and that it should be possible to administer a larger dose of 400 mg without fear of approaching toxic concentrations. Furthermore, we have obtained some evidence that lignocaine 200 mg was associated with a measurable analgesic effect, although of modest clinical magnitude. Thus this preliminary study suggests that the technique is safe, and that it is worthwhile examining the use of larger doses of lignocaine and also bupivacaine for analgesia after total abdominal hysterectomy.

# Pre-anaesthetic assessment of coagulation abnormalities in obstetric patients: usefulness, timing and clinical implications

L. SIMON, T. M. SANTI, P. SACQUIN AND J. HAMZA

## Summary

The usefulness and optimal timing of laboratory coagulation tests before obstetric extradural analgesia are controversial. Moreover, the significance of mild coagulation abnormalities during pregnancy remains unclear. We have assessed the reliability of coagulation tests performed several weeks before delivery as predictors of coagulation abnormalities during labour. Platelet count, plasma fibrinogen concentration, prothrombin time (PT) and activated partial thromboplastin time (aPTT) were sampled in 797 women during the ninth month of pregnancy and checked during labour. Platelet count was less than $100 \times 10^9$ litre$^{-1}$ for 11 women during labour. Only three had been detected by the first sample. Platelet count less than $100 \times 10^9$ litre$^{-1}$ or fibrinogen concentration less than 2.9 g litre$^{-1}$ during labour were associated with an increase in the incidence of postpartum haemorrhage (odds ratio=19.7). We conclude that a platelet count several weeks before delivery was not reliable in predicting thrombocytopenia during labour and that women with mild coagulation abnormalities in early labour may need special attention regarding the risk of postpartum haemorrhage. (*Br. J. Anaesth.* 1997; **78**: 678–683).

**Key words**
Anaesthesia, obstetric. Anaesthetic techniques, extradural. Blood, haemostasis. Blood, coagulation.

In a recent survey of 435 French obstetric units,[1] most anaesthetists advocated laboratory coagulation tests before extradural analgesia for labour. In this study, coagulation tests were performed during the ninth month of pregnancy in 74% of obstetric units surveyed. They included prothrombin time (PT), activated partial thromboplastin time (aPTT) and platelet count in almost all cases. Although haemostasis disorders seem to increase the risk of extradural haematoma,[2] the usefulness of laboratory coagulation screening tests is still debatable.[3] However, platelet count can decrease during pregnancy[4] and the incidence of thrombocytopenia has been shown to increase during labour.[5] The significance of this thrombocytopenia remains unclear and determination of a safe lower platelet count limit before performing extradural analgesia is still controversial. Many anaesthetists avoid extradural analgesia if platelet count is less than $100 \times 10^9$ litre$^{-1}$,[6–8] but this limit has no supporting data.[9] Another difficulty in coagulation assessment is the choice of when to perform it. Haemostasis disorders can appear late in pregnancy. Therefore, a medical history, physical examination and laboratory testing may be inadequate in detecting these haemostasis disorders if they are performed too early.[10] In addition, no relationship between mild coagulation abnormalities during pregnancy and haemorrhagic complications during extradural analgesia[11] or delivery[12] have yet been established.

Therefore, we designed a prospective study to evaluate the accuracy of laboratory coagulation tests performed during the ninth month of pregnancy to predict coagulation abnormalities during labour. We also examined the incidence of these coagulation abnormalities during labour and their relationship with post-partum haemorrhage (PPH).

## Patients and methods

This prospective surveillance study was performed between 1 June 1995 and 31 December 1995. During this period, we studied all women with a singleton pregnancy who came into the labour ward for delivery. As the study was an anonymous survey of haematological and clinical variables, hospital Ethics Committee approval was not required. Inclusion criteria were: pre-anaesthetic clinical assessment during the ninth month of pregnancy, physical status ASA I or II, and term >36 and <42 weeks at the time of delivery. We excluded all women with a medical history known to be associated with haemostasis disorders, such as von Willebrand disease, diabetes mellitus, idiopathic thrombocytopenic purpura or lupus erythematosus. We also excluded women receiving anticoagulant therapy and parturients admitted for elective Caesarean section.

Accepted for publication: January 28, 1997.

### STUDY DESIGN

The first blood sample (BS 1) for laboratory coagulation tests was obtained in each parturient during the ninth month of pregnancy, usually just after pre-anaesthetic clinical assessment. Platelet count, PT, aPTT and plasma fibrinogen concentration were determined in each sample. When the women entered the labour ward for delivery, a second blood sample (BS 2) was obtained for the same tests via a 16-gauge i.v. cannula just before the start of a basal infusion of Ringer's lactate solution. Age, parity, medical and obstetric history, and gestational age (GA) were obtained by an anaesthetist, who enquired again of any previous history of bleeding. He also noted on the anaesthetic chart all recent antepartum medical complications such as pre-eclampsia, sepsis or placenta praevia. Each abnormal coagulation test result was checked systematically in a new sample. Moreover, thrombocytopenia (platelet count $<100\times10^9$ litre$^{-1}$) was confirmed by examination of the stained peripheral blood film to exclude platelet clumping. BS 2 was always available before the decision to proceed with extradural analgesia. If indicated, extradural analgesia was provided for labour in each parturient whose platelet count was more than $100\times10^9$ litre$^{-1}$ at BS 2.

When the women left the labour ward, the route of delivery (vaginal delivery or Caesarean section) and the occurrence of PPH were noted. Only significant haemorrhages were considered. These were defined as clinically severe bleeding requiring volume expansion and manual uterine exploration, associated with either blood transfusion or a significant decrease ($\geqslant2$ g dl$^{-1}$) in haemoglobin concentration, or both, within 24 h post-partum.

We compared for each parturient the results of BS 1 and BS 2, and we calculated the changes in platelet count (%) and fibrinogen concentration (g litre$^{-1}$) between the two periods. Then we examined mean (SD) platelet count and fibrinogen concentration in BS 2. Values less than the lower threshold of the corresponding 95% confidence limits (value $\leqslant$mean value $-1.96$ SD) for one or both variables, or with a PT <70% or an aPTT >40 s (normal 30 s) were classified as "coagulation abnormalities". We compared the incidence of severe PPH in this group and in the other women.

### STATISTICAL ANALYSIS

Results are expressed as mean (SD). For quantitative data, statistical analysis was performed using analysis of variance for repeated measures. When overall differences were detected, individual comparisons between groups were performed by Student's *t* test with Bonferroni's correction. Fisher's exact test was used to compare nominal data.

## Results

We studied 835 parturients: 797 were included in the results and statistical analyses, and 38 were excluded. The characteristics of these 38 patients in the labour ward are shown in table 1. Mean delay between BS 1 and BS 2 was 17 (9) days (always less than 30 days).

*Table 1* Information on 38 women excluded from the study. Reasons for exclusion are indicated

| | |
|---|---|
| *n* | 38 |
| Age (yr) (mean (range)) | 30.9 (24–43) |
| Gestational age (weeks) (mean (SD)) | 38.2 (2.4) |
| Reasons for exclusion in labour ward | |
| Placenta praevia | 8 |
| Placenta abruptio | 2 |
| Fever >38.5°C ± sepsis syndrome | 6 |
| BS 2 not available | 10 |
| Low molecular weight heparin therapy | 3 |
| Hypertension and/or pre-eclampsia | 9 |

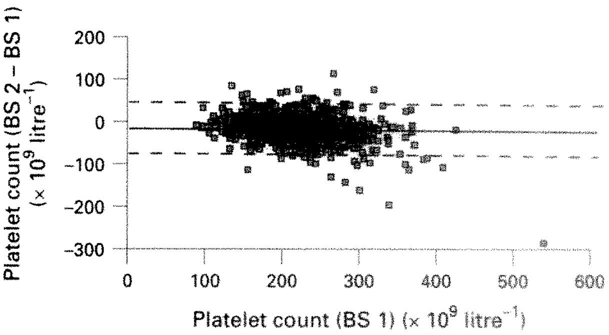

*Figure 1* Variations (in absolute value) in platelet count between the two samples, BS 1 and BS 2, for each woman. These variations (Y axis) in function of the BS 1 value for platelet count (X axis) are shown. Mean variation (—) and 95% confidence limits (- - -) for these variations are also indicated.

### PLATELET COUNT

Mean values for platelet count in BS 1 and BS 2

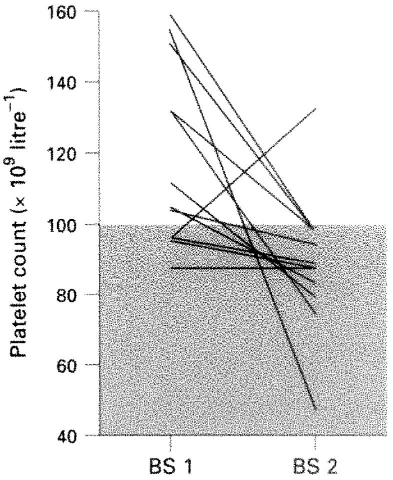

*Figure 2* Variations (in absolute value) in platelet count between the two samples, BS 1 and BS 2, for women who had a platelet count less than $100\times10^9$ litre$^{-1}$ (mean value $-1.96$ SD at BS 2) in either one or both samples. The shaded area indicates the area below $100\times10^9$ litre$^{-1}$.

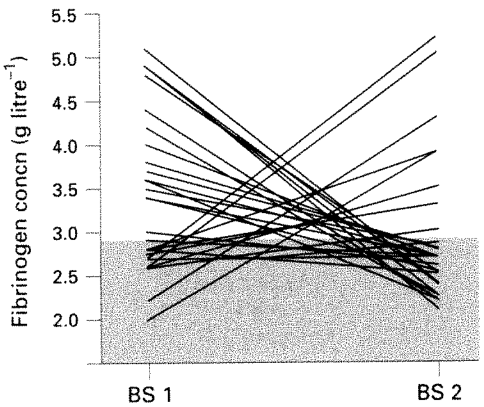

*Figure 3* Variations (in absolute value) in plasma fibrinogen concentration between the two samples, BS 1 and BS 2, for women who had a plasma fibrinogen concentration less than 2.9 g litre$^{-1}$ (mean value $-1.96$ SD at BS 2) in either one or both samples. The shaded area indicates the area below 2.9 g litre$^{-1}$.

were, respectively, 216 (54)$\times10^9$ litre$^{-1}$ (extremes 88–538) and 206 (54)$\times10^9$ litre$^{-1}$ (extremes 48–415). From BS 1 to BS 2, platelet count was variable and unpredictable in all women (fig. 1).

The lower threshold of the 95% confidence limit for platelet count was $100\times10^9$ litre$^{-1}$ (BS 2 mean value $-1.96$ SD$=206-(1.96\times54)=100\times10^9$ litre$^{-1}$). Four women were thrombocytopenic ($<100\times10^9$ litre$^{-1}$) at BS 1. For one patient, platelet count increased to $132\times10^9$ litre$^{-1}$ at BS 2, whereas for the others, platelet count at BS 2 remained less than $100\times10^9$ litre$^{-1}$. Thrombocytopenia ($<100\times10^9$ litre$^{-1}$) appeared in eight other women at BS 2. Therefore, a total of 11 women had platelet counts less than $100\times10^9$ litre$^{-1}$ at BS 2. All of these parturients had platelet counts less than $160\times10^9$ litre$^{-1}$ at BS 1 (fig. 2). Mean variation between the two samples was $-26$ (20) % for these 11 thrombocytopenic patients whereas it was $-3.7$ (14) % in the overall population.

### PT, aPTT AND PLASMA FIBRINOGEN CONCENTRATION

There were no abnormal values for PT or aPTT in either BS 1 or BS 2. Mean values for fibrinogen concentrations in BS 1 and BS 2 were, respectively, 4.6 (0.8) g litre$^{-1}$ (extremes 2.0–7.6) and 4.8 (1.0) g litre$^{-1}$ (extremes 2.1–9.0). The lower threshold of the 95% confidence limit for plasma fibrinogen concentration was 2.9 g litre$^{-1}$ (BS 2 mean value $-1.96\times$SD). Thirteen parturients had fibrinogen concentrations less than 2.9 g litre$^{-1}$ at BS 1. Twenty-six parturients had fibrinogen concentrations less than 2.9 g litre$^{-1}$ at BS 2. For these women, the variation in fibrinogen concentration from BS 1 to BS 2 was $-1.23$ (0.88) g litre$^{-1}$, whereas it was $+0.18$ (0.84) g litre$^{-1}$ in the overall population. As observed with platelet count, BS 1 was not reliable in detecting women with fibrinogen concentrations less than 2.9 g litre$^{-1}$ at BS 2 (fig. 3).

### COAGULATION DISORDERS IN EARLY LABOUR AND PPH

The mode of delivery was vaginal for 677 women and a Caesarean section was performed in the other 120. Among the 677 who had a vaginal delivery, 46 had significant PPH (table 2) and all occurred in patients asymptomatic for haemostasis disorders before delivery. They were all considered as clinically significant haemorrhages requiring volume expansion (Ringer's solution, blood transfusion, or both) and manual uterine exploration. In two patients, hysterectomy was necessary to stop massive haemorrhage. Mean

*Table 2* Number of patients and main clinical characteristics of women who had Caesarean section or vaginal delivery with or without post-partum haemorrhage (PPH). *$P<0.05$ *vs* value in women who had vaginal delivery with no PPH (Student's *t* test)

| | | Vaginal delivery | |
|---|---|---|---|
| | Caesarean sections | PPH | No PPH |
| *n* | 120 | 46 | 631 |
| Age (yr) (mean (range)) | 32.7 (21–45) | 30.9 (21–41) | 31.5 (19–46) |

| Fibrinogen level (g litre$^{-1}$) | 5.0 (0.9) | 4.3 (1.3)* | 4.9 (1.0) |

*Table 3* Sensitivity specificity, positive and negative predictive values of fibrinogen concentration <2.9 g litre$^{-1}$, at either BS 1 or BS 2, predicting occurrence of PPH

| | Sensitivity (%) | Specificity (%) | Positive predictive value (%) | Negative predictive value (%) |
|---|---|---|---|---|
| Fibrinogen <2.9 g litre$^{-1}$ at | | | | |
| BS 1 | 4.3 | 98.4 | 16.6 | 93.4 |
| BS 2 | 19.6 | 97.8 | 39.1 | 94.3 |

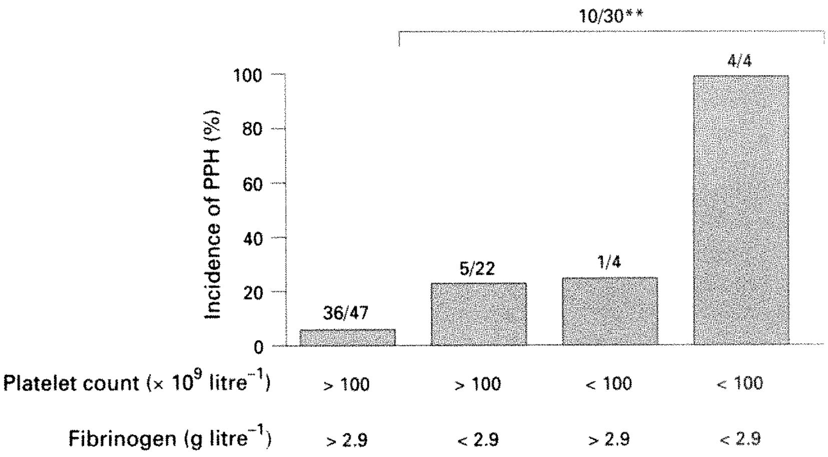

*Figure 4* Incidence of post-partum haemorrhage (PPH) in women with platelet counts or fibrinogen concentrations at BS 2 less than $100 \times 10^9$ litre$^{-1}$ and 2.9 g litre$^{-1}$, respectively. The incidence was significantly different compared with the rate observed in women with both platelet count and fibrinogen concentrations greater than these thresholds (**$P<0.01$; Fischer's exact test). Rates are indicated in percent (Y axis) and absolute values.

decrease in haemoglobin concentration within 24 h post-partum was 4.0 (1.5) g dl$^{-1}$ for these 46 patients.

Platelet count and fibrinogen concentration at BS 2 were significantly lower in women with PPH than in those who did not bleed (table 2). If one or both of these variables were below the corresponding "mean value −1.96 SD" threshold, the incidence of PPH was increased significantly compared with the other women (fig. 4). Sensitivity, specificity, positive and negative predictive values for both BS 1 and BS 2 for low fibrinogen predicting subsequent PPH are presented in table 3.

## Discussion

In our study, the percentage of women with platelet count values less than $100 \times 10^9$ litre$^{-1}$ and less than $150 \times 10^9$ litre$^{-1}$ increased, respectively, from 0.5 to 1.4% and from 7.3 to 12.4% between BS 1 and BS 2. These results are in agreement with those of Rolbin and colleagues who measured platelet count in 1621 healthy women.[9] Only seven (0.4%) and 104 (6.4%) had platelet counts less than 100 and $150 \times 10^9$ litre$^{-1}$, respectively. However, these results were obtained either during pregnancy or in the post-partum period. All patients were asymptomatic, but some had significant thrombocytopenia (lower platelet count $21 \times 10^9$ litre$^{-1}$). Burrows and Kelton found in 1357 healthy women an incidence of 8.3% asymptomatic mild thrombocytopenia (97–$150 \times 10^9$ litre$^{-1}$) during labour.[5]

Gestational thrombocytopenia is quite common but its significance is still unclear. The decrease in platelet count could be related to haemodilution and acceleration of platelet turnover with increased production of platelets from the bone marrow and increased trapping or destruction at the placental level. This quantitative decrease in platelet count could be counterbalanced by a marked increase in platelet reactivity during pregnancy.[13] On the other hand, some authors have described decreased platelet activation during pregnancy[14 15] and suggested the presence of a plasma factor that selectively inhibits prostaglandin-dependent activation.[15] Therefore, it remains difficult in clinical practice to define precisely the clotting capacities of a woman with a mild gestational thrombocytopenia.

The risk of spinal haematoma has been estimated to be approximately 1 in 150 000 after extradural analgesia.[2] Even if the risk of this complication is increased in patients with a low platelet count, it is difficult to define the safe lower threshold for platelet count. The haematological definition of thrombocytopenia is a platelet count less than $150 \times 10^9$ litre$^{-1}$. The lower limit of $100 \times 10^9$ litre$^{-1}$ for platelet count, often judged as "safe" to perform extradural analgesia,[6–8] has no supporting data. In the absence of any other coagulation disorder, some authors would prefer to lower this limit to $80 \times 10^9$ litre$^{-1}$.[16] Nevertheless, some authors do not systematically observe the platelet count before extradural analgesia.[7 8] Rolbin and colleagues estimated that in their institution approximately 5000 thrombocytopenic parturients have benefitted from extradural analgesia over a 30-yr period without any spinal haematomas.[9] The same team has reported the case of uncomplicated extradural analgesia in an asymptomatic parturient whose platelet count was $2 \times 10^9$ litre$^{-1}$ immediately after delivery.[7]

Whatever the significance of these low platelet counts and the acceptable limit, one remaining problem is the choice of the appropriate time to perform a platelet count. Indeed, some authors found a decrease in mean platelet count whereas others reported no change in platelet count during pregnancy.[17] Many anaesthetists consider it sensible to obtain the results of coagulation tests several weeks before extradural analgesia.[1] However, our study showed that the result of this nine month platelet count was useless in predicting platelet count less than $100 \times 10^9$ litre$^{-1}$ during labour.

The nature of the other laboratory tests which are useful before extradural analgesia and their lower "safe value" are still debatable. Coagulation tests such as PT and aPTT measurements have not been studied extensively in obstetric patients but they seem to be less useful for early detection of haemostasis disorders during labour.[18] Indeed, these tests were always normal in our study. Therefore, we believe that these tests should no longer be performed in clinically normal parturients before extradural analgesia.

Fibrinogen concentration increases physiologically during pregnancy.[19 20] A safe lower limit for plasma fibrinogen concentration has not been evaluated, while the safe laboratory lower limit defined for the general population may not be appropriate for pregnant women. Nevertheless, we had to define a lower limit of normality for both of these variables. Therefore, all values for either platelet count or fibrinogen concentration at BS 2 which were below the lower threshold of the corresponding 95% confidence limit were considered as abnormal.

Our study has shown that significant PPH were more frequent when platelet count or fibrinogen concentration, or both, were low in early labour. In previous studies, this association has not been recognized as a significant factor associated with PPH.[12] The significance of the relationship between these mild coagulation abnormalities and the occurrence of PPH is not clear. During pregnancy, biological changes occur such as an increase in many clotting factor concentrations and placental synthesis of plasminogen activator inhibitor. Early in pregnancy, intravascular fibrin deposition can be found in the uteroplacental circulation.[19] This reflects local chronic intravascular coagulation which induces local fibrinolysis.[21 22] These biological changes are associated with mechanical factors that limit the risk of bleeding, such as structural changes in the spiral arteries and myometrial contractions.[6 19] These physiological changes must prepare the pregnant woman for delivery and placental separation and the inherent risk of haemorrhage. In case of failure of the mechanical protective mechanisms, there is an increased need for haemostatic components such as fibrinogen and platelets. We may hypothesize that in such situations there is inadequate compensation which is reflected in a low platelet count and a low fibrinogen plasma concentration. Combs, Murphy and Laros showed that the main clinical variables related to the risk of PPH were prolonged labour and factors associated with uterine atony.[12] If impaired uterine contractility occurred in patients with a low platelet count and fibrinogen concentration, local coagulation factors may not ensure good haemostasis and therefore, at the time of delivery, an increased incidence of PPH could occur. This hypothesis of a relationship between obstetric factors and mild coagulation abnormalities may explain the occurrence of PPH, but this will require further studies.

In clinical practice, detection of coagulation abnormalities, and especially detection of thrombocytopenia, may be important in the management of the obstetric patient. Nevertheless, unhelpful coagulation tests should be avoided. Our results demonstrated that coagulation tests performed several weeks before labour should be abandoned and that PT and aPTT are unnecessary in clinically normal parturients.

# Effect of progressive haemodilution with hydroxyethyl starch, gelatin and albumin on blood coagulation

G. A. Egli, A. Zollinger, B. Seifert, D. Popovic, T. Pasch and D. R. Spahn

## Summary

We have compared the effects of progressive (30% and 60%) *in vitro* haemodilution with hydroxyethyl starch (HES), gelatin (GEL) and albumin (ALB) with haemodilution using 0.9% saline in 96 patients by thrombelastography. Haemodilution with HES, GEL and ALB significantly ($P<0.05$) compromised coagulation time ($k$), angle $\alpha$ and maximal amplitude (MA), with HES having the most negative effect at 30% and 60% haemodilution ($P<0.05$). Haemodilution with saline significantly affected all variables of blood coagulation and clot lysis measured by thrombelastography, resulting in an increased coagulability at 30% haemodilution. To specifically assess the intrinsic effect of plasma expander molecules on blood coagulation and clot lysis, we analysed the difference between saline diluted blood (same degree of haemodilution) and plasma expander diluted blood. Prolongation of reaction time ($r$) was found for HES at 30% and 60% haemodilution and for ALB at 60% haemodilution and an increase in clot lysis by HES, GEL and ALB became evident. We conclude that HES, GEL and ALB compromised blood coagulation, while the maximum effect was found with HES. (*Br. J. Anaesth.* 1997; **78**: 684–689).

**Key words**
Blood, haemodilution. Measurement techniques, thrombelastography. Blood, coagulation. Blood, replacement.

In recent years there has been increasing awareness of the potential side effects of allogeneic blood products.[1] With increasing use of artificial plasma expanders, their influence on blood coagulation may become clinically relevant.[2] However, assessing the influence of various plasma expanders on blood coagulation is difficult because the observed effect may be a result of an intrinsic effect of the plasma expander molecules in addition to an effect of haemodilution on blood coagulation *per se*. Haemodilution may not necessarily compromise blood coagulation. In contrast, haemodilution with crystalloids may even increase blood coagulation as shown *in vitro*[3] and *in vivo*.[4–6] To standardize the degree of haemodilution and, in particular, to distinguish between the effect of plasma expanders and the effect of haemodilution *per se*, we have assessed *in vitro* the effect of hydroxyethyl starch, gelatin and albumin on blood coagulation compared with saline diluted blood samples using thrombelastography.

## Patients and methods

With approval of the Ethics Committee, a 10-ml blood sample was collected from 126 patients undergoing various surgical procedures. In a pilot study (30 patients) blood was collected during induction of anaesthesia and in the main study (96 patients) blood was collected before induction. Exclusion criteria were known coagulation disorders, prothrombin time less than 85%, non-steroidal anti-inflammatory agents (NSAID) within 24 h before surgery, oral anticoagulation, acetylsalicylic acid (ASA) within 5 days before operation, known liver diseases or increased plasma concentrations of aspartate aminotransferase (AST>50 iu litre$^{-1}$) or alanine aminotransferase (ALT>50 iu litre$^{-1}$), and known renal diseases or increased creatinine concentration (creatinine>120 μmol litre$^{-1}$). Standard thrombosis prophylaxis of low molecular weight heparin administered s.c. (3000 IE, Sandoparin) the evening before surgery was allowed.

Blood coagulation was assessed by thrombelastography (CTEG #3000, Haemoscope, Morton Grove, IL, USA). Whole blood (0.36 ml) is placed in a cuvette which is rotated back and forth. A piston is suspended in the blood, and as coagulation proceeds, fibrin strands form between the walls of the cuvette and the piston. The piston thus becomes increasingly coupled to the motion of the cuvette, and hence the shearing elasticity of the evolving blood clot is detected to yield the TEG trace.[3 6] This TEG trace is described by specific variables. Reaction time ($r$) is the interval between the start of the recording until an amplitude of 2 mm is reached (normal value 12.0 (2.3) mm). It reflects the function of the coagulation factors. Coagulation time ($k$)

is defined as the time interval from the end of *r* until the amplitude of the TEG tracing reaches 20 mm (normal value 4.2 (1.6) mm); *k* is influenced not only by coagulation factors but also by fibrinogen and the number and function of platelets. Maximum amplitude (MA) of the TEG tracing reflects clot strength as a function of platelets and fibrinogen (normal value 63.5 (4.5) mm). The angle $\alpha$ is formed by the slope of the TEG tracing from the *r* to the *k* value and is, similarly to MA, influenced by the function of platelets and fibrinogen (normal value 60.2 (6.7) °). Clot lysis can be described by the clot lysis index (CLI), defined as the amplitude of the TEG trace at 60 min after MA (A60) divided by MA (CLI=A60/MA×100, %) or by Ly30 and Ly60.[7] The fibrinolysis indexes, Ly30 and Ly60, computed by the current TEG device, are defined as the percentage reduction of the computed area under the curve 30 and 60 min after reaching MA (normal value for Ly30<7.5 % and Ly60<15%). All normal values apply to plastic cups and plastic pins with 1% celite activation (CTEG manual, Haemoscope Corporation, 1990).

The following volume expanders were investigated: hydroxyethyl starch 200 000/0.5 (HES) (Isohes 6%, Laevosan International AG, Zurich, Switzerland), succinylated gelatin (GEL) (Physiogel 4%, Braun Medical, Emmenbrücke, Switzerland) and 5% human serum albumin (ALB) (ZLB Zentrallaboratorium Blutspendedienst SRK, Bern, Switzerland). In pilot studies (30 patients), we found that sodium bicarbonate and $CaCl_2$ had to be added to all volume expanders and also to 0.9% saline such that physiological pH and ionized $Ca^{2+}$ values resulted after *in vitro* haemodilution. However, the amount of sodium bicarbonate and $CaCl_2$ was not the same for different volume expanders. Thus we defined (pre-haemodilution) ranges for pH and ionized $Ca^{2+}$ for all volume expanders and 0.9% saline which resulted in physiological pH and physiological ionized $Ca^{2+}$ after *in vitro* haemodilution. The following ranges were found: HES (pH 6.66–6.92; $Ca^{2+}$ 1.22–1.29 mmol litre$^{-1}$), GEL (pH 7.28–7.40; $Ca^{2+}$ 1.24–1.29 mmol litre$^{-1}$), ALB (pH 7.10–7.24; $Ca^{2+}$ 1.32–1.38 mmol litre$^{-1}$) and saline (pH 6.88–7.45, $Ca^{2+}$ 1.18–1.24 mmol litre$^{-1}$). Adjusting pH and calcium concentration of all volume expanders and 0.9% saline *in vitro* before haemodilution is important because *in vitro* there are no effective homeostatic mechanisms preventing relevant changes in pH and electrolyte concentrations caused by haemodilution with crystalloids or colloids. Without such a correction blood coagulation would have been impaired by low ionized $Ca^{2+}$ and low pH.[8–11]

Blood samples from 96 patients were allocated randomly to one of six groups ($n$=16) to be haemodiluted with HES, GEL or ALB, either by 30% or 60%. In each patient, blood coagulation was assessed simultaneously in native blood, after haemodilution with a volume expander and also after haemodilution to the same degree with saline (see below).

Foaming or frothing was prevented carefully during blood sampling. The first 2 ml were discarded and then 8 ml were sampled in polypropylene syringes. With reverse pipetting the appropriate amount of blood was filled into prewarmed (37.0 °C) polypropylene tubes containing volume expander or saline to prevent cooling of the blood volume expander mixture which might compromise blood coagulation.[11 12] Mixing was performed carefully by filling and half-emptying the pipette five times. The same procedure was performed with native blood so as to prevent activation of the coagulation system through handling. Three minutes after mixing, 1 ml of native blood, 1 ml of volume expander diluted blood and 1 ml of saline diluted blood were filled into tubes containing 1% celite.[13] One minute later (4–5 min after blood withdrawal), 360 µl were pipetted into the thrombelastographic cups. Exactly 6 min after withdrawal of blood, thrombelastography was started.[7] Plastic pins and plastic cups used were put in the TEG at least 10 min before starting the assay. The temperature of the TEG was maintained at 37.0 °C. The remainder of the native and diluted blood was used for blood-gas, electrolyte and haemoglobin measurements (BGElectrolytes and CO-Oximeter, Instrumentation Laboratory, Lexington, MA, USA and Electrolyte 8 Analyser, Nova Biomedica, Waltham, MA, USA).

Unpaired *t* tests were used to compare patient characteristics (Statview 4.02, Abacus Concepts, Inc., Berkeley, CA). Changes caused by *in vitro* haemodilution were analysed by repeated measures analysis of variance (ANOVA) with Greenhouse–Geisser correction (Superanova 1.11, Abacus Concepts, Inc., Berkeley, CA, USA). When this overall ANOVA resulted in a significant haemodilution and plasma expander effect, respectively, *post hoc* paired and unpaired *t* tests with Bonferroni correction were performed. Data are presented as mean (SD) and mean (SEM) as appropriate. $P<0.05$ was considered statistically significant.

## Results

Three were no differences in the HES, GEL and ALB groups in patient characteristics (table 1) or baseline data (table 2, figs 1, 3).

Haemodilution with HES, GEL, ALB and saline resulted in a similar decrease in haemoglobin concentration (table 2). Ionized $Ca^{2+}$ concentration was stable during haemodilution in the HES and GEL groups but decreased minimally in the ALB group at

30% and 60% haemodilution (table 2). pH was stable during haemodilution with ALB and decreased minimally during haemodilution with HES and GEL (table 2). Also, during haemodilution with saline, the ionized $Ca^{2+}$ concentration and pH decreased minimally at 30% and 60% haemodilution (table 2). However, ionized $Ca^{2+}$ concentration and pH were within the physiological range after haemodilution with all volume expanders and saline (table 2).

Compared with native blood, progressive haemodilution with HES, GEL and ALB did not affect reaction time (*r*) (fig. 1A) but compromised the rapidity of clot formation, as manifested by an increase in coagulation time (*k*) and a decrease in the clot formation rate (angle α) (fig. 1B, C). With HES, this was significant at 30% haemodilution; with GEL and ALB, significant changes were observed only at 60% haemodilution. The strength of the clot (MA) was decreased by HES, GEL and ALB at 30% and 60% haemodilution (fig. 1D). Thus HES had the most negative effect on *k*, angle α and MA. Clot lysis at 30 or 60 min was not affected by haemodilution (fig. 1E, F). No individual patient had pathological clot lysis caused by haemodilution, that is Ly30>7.5 % or Ly60>15%.

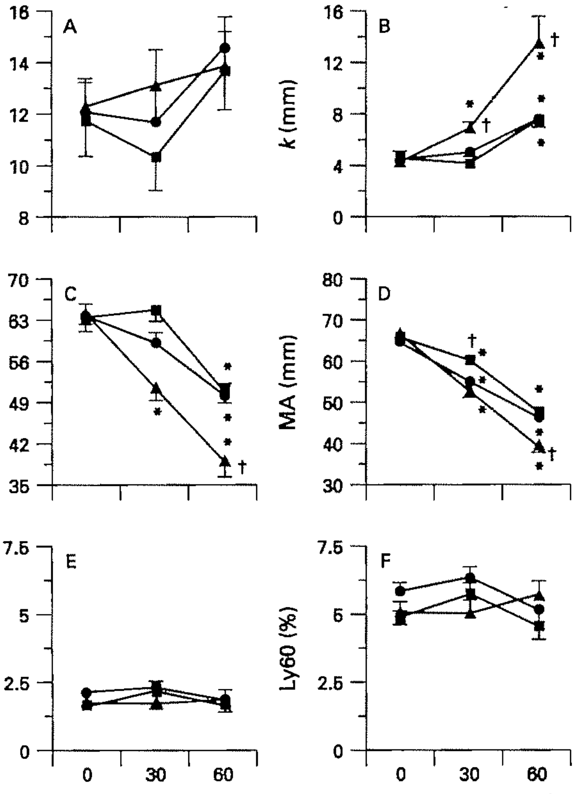

*Figure 1* Effect of progressive (30%, 60%) *in vitro* haemodilution with hydroxyethyl starch (▲), gelatin (●) and albumin(■) on blood coagulation, as assessed by thrombelastography: reaction time (*r*) (A), coagulation time (*k*) (B), angle α (Ang α) (C), maximal amplitude (MA) (D), lysis after 30 min (Ly30) (E) and lysis after 60 min (Ly60) (F). Data are mean (SEM). Significantly different (*$P<0.05$) from native blood; significantly different (†$P<0.05$) from other groups.

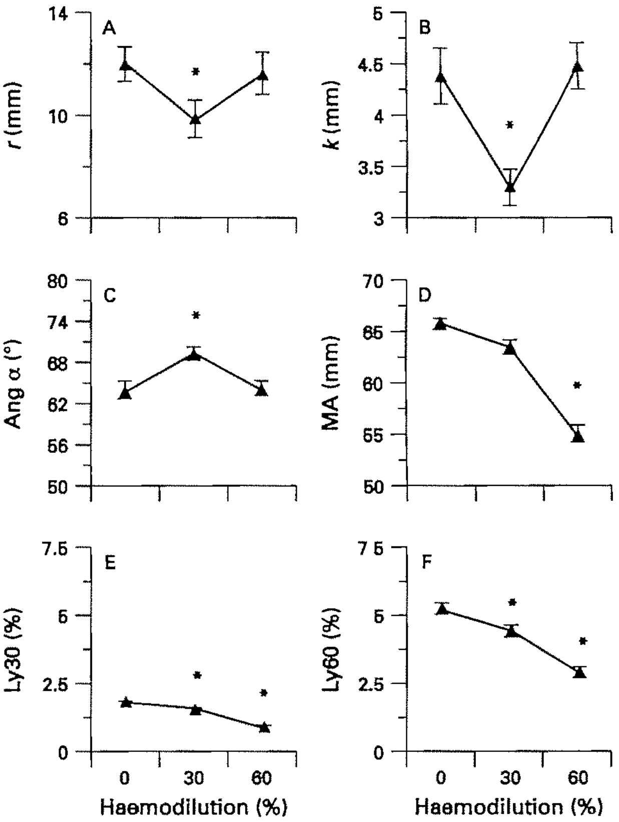

*Figure 2* Effect of progressive (30%, 60%) *in vitro* haemodilution with saline (▲) on blood coagulation as assessed by thrombelastography: reaction time (*r*) (A), coagulation time (*k*) (B), angle α (Ang α) (C), maximal amplitude (MA) (D), lysis after 30 min (Ly30) (E) and lysis after 60 min (Ly60) (F). Data are mean (SEM). Significantly different (*$P<0.05$) from native blood.

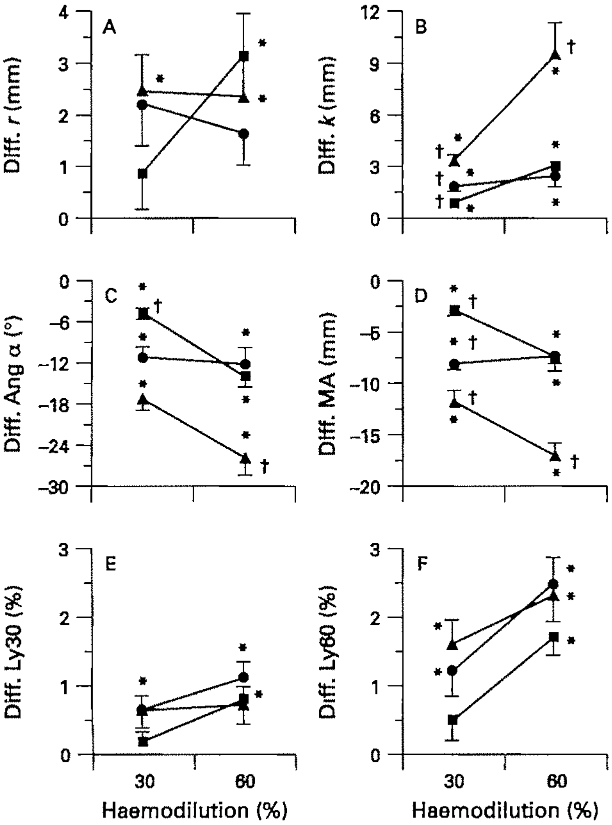

*Figure 3* Effect of progressive (30%, 60%) *in vitro* haemodilution with hydroxyethyl starch (▲), gelatin (●) and albumin(■) on blood coagulation as assessed by thrombelastography in comparison with haemodilution with 0.9% saline, expressed as absolute difference (Diff.) of values (expander minus saline): reaction time (Diff. *r*) (A), coagulation time (Diff. *k*) (B), angle α (Diff. Ang α) (C), maximal amplitude (Diff. MA) (D), lysis after 30 min (Diff. Ly30) (E) and lysis after 60 min (Diff. Ly60) (F). Data are mean (SEM). Significantly different (*$P<0.05$) from 0; significantly different (†$P<0.05$) from other groups.

To specifically assess the intrinsic effect of plasma expander molecules on blood coagulation, we first analysed the effect of haemodilution with saline *per se* (compared with native blood). At 30% haemodilution, reaction time (*r*) and coagulation time (*k*) decreased and clot formation rate (angle α) increased. At 60% haemodilution, all three variables recovered (fig. 2A–C). MA was compromised at 60% haemodilution, and clot lysis at 30 and 60 min (Ly30 and Ly60) showed progressive decrease with increasing haemodilution (fig. 2D–F).

The intrinsic effect of plasma expander molecules on blood coagulation may thus be assessed by analysing the difference between saline diluted blood (same degree of haemodilution) and plasma expander diluted blood. Haemodilution with HES resulted in a longer reaction time (*r*) at 30% and 60% haemodilution compared with saline haemodilution, and ALB resulted in a longer reaction time (*r*) at 60% haemodilution (fig. 3A). Coagulation time (*k*) was prolonged by haemodilution with HES, GEL and ALB at 30% and 60% haemodilution compared with saline haemodilution (fig. 3B), and also clot formation rate (angle α) was less during 30% and 60% haemodilution using HES, GEL and ALB than during haemodilution with saline (fig. 3C). Furthermore, the decrease in the strength of the clot, that is the decrease in MA, was more pronounced during 30% and 60% haemodilution with HES, GEL and ALB compared with haemodilution using saline (fig. 3D). HES had the most negative effect on *k*, angle α and MA. Haemodilution with GEL and ALB resulted in increased clot lysis at 30 min (Ly30) in comparison with haemodilution with saline (fig. 3E), and clot lysis at 60 min (Ly60) was increased more during haemodilution with HES, GEL and ALB compared with haemodilution with saline (fig. 3F).

There were no differences between patients with and without cancer, either at baseline or at any degree of haemodilution with any volume expander tested (data not shown).

## Discussion

We have demonstrated that blood coagulation was compromised by *in vitro* haemodilution using hydroxyethyl starch, gelatin or albumin. However, hydroxyethyl starch had the most pronounced effect. Also, when the effect of haemodilution with saline is considered, hydroxyethyl starch, gelatin and albumin also increased clot lysis.

Because of increasing awareness of the potential side effects of allogeneic blood products, volume expanders are used increasingly to treat surgical blood loss.[1] Thus the side effects of volume expanders such as interference with blood coagulation may become clinically relevant. In this study we found that while hydroxyethyl starch had the most pronounced effect, *all* volume expanders showed qualitatively similar effects, namely a marked decrease in the strength of the clot (MA) and rapidity of clot formation (angle α), and also an increase in coagulation time (*k*) (figs 1, 3). This pattern is compatible with platelet dysfunction[14] and with previous reports of a decrease in all factor VIII moieties produced by hydroxyethyl starch and dextran infusions,[15–20] which might result in platelet dysfunction.[21] However, the decrease in factor VIII was not observed when dextran or hydroxyethyl starch was added *in vitro*.[17 22] These *in vitro* studies, however, were performed in citrated plasma to prevent clotting and thus may not be representative of the present study because blood coagulation in this study was not inhibited but progressed during thrombelastography measurement. When blood coagulation is not inhibited, hydroxyethyl starch and dextran solutions can precipitate coagulation factors also *in vitro*[23] and thus compromised blood coagulation during haemodilution might be caused by reduced clotting factor activity, in particular factor VIII.

We found significant impairment of blood coagulation with hydroxyethyl starch but also with albumin and gelatin (figs 1, 3). Thus during profound haemodilution, blood coagulation may be compromised irrespective of the volume expander used. Indeed, recent data suggest that abnormal haemostasis may develop before compromise of global tissue oxygen delivery and consumption.[2]

The effects of plasma expanders on clot lysis have not been investigated fully. In the presence of hydroxyethyl starch, faster transformation of fibrinogen to fibrin has been shown.[24 25] This fibrin was shown to be less stable as evidenced by a shortened urokinase-activated clot lysis time suggesting enhanced fibrinolysis.[24 25] Also, gelatin has been shown to be incorporated into developing blood clots and thus potentially interfere with fibrin polymerization.[26] Similarly, we also found progressively augmented clot lysis for all three plasma expanders compared with saline. This effect, however, was apparent only when the influence of haemodilution with saline *per se* on clot lysis was taken into account (fig. 3). Despite this augmentation, clot lysis was, on average, still within normal ranges and thus may be of limited clinical relevance.

Interestingly, moderate haemodilution with crystalloids appeared to augment blood coagulation (fig. 2) which is in keeping with earlier *in vitro*[3] and *in vivo* observations.[4–6] Recently, Ruttmann, James and Viljoen[3] described a hypercoagulable state at 20% haemodilution with saline, as evidenced by a shortened reaction time (*r*) and an increased rapidity of clot formation (*k* and angle $\alpha$). At 30% haemodilution with saline, we also found a shortened reaction time (*r*) and increased rapidity of clot formation (*k* and angle $\alpha$) (fig. 2). At 30% haemodilution with gelatin, however, we did not observe such an augmentation of blood coagulation (fig. 1) compared with Ruttmann, James and Viljoen,[3] who also described a shortened reaction time (*r*) and increased rapidity of clot formation (*k* and angle $\alpha$) at 20% haemodilution with gelatin. The difference might be explained by the more profound degree of haemodilution produced in this study. Interestingly, although we did not observe a hypercoagulable state at 30% haemodilution with gelatin, *k* and angle $\alpha$ were unchanged and became compromised only at 60% haemodilution, indicating that the degree of haemodilution may be crucial for changes in blood coagulation during haemodilution.

The mechanisms by which blood coagulation is facilitated during moderate haemodilution with saline are largely unknown. One might hypothesize, however, that the anticoagulant activity of blood may be compromised more than the procoagulant activity during moderate haemodilution, resulting in a hypercoagulable state. With advanced haemodilution also, procoagulant activity may become diluted and the net result at profound haemodilution is compromised blood coagulation, as observed in this study at 60% haemodilution (fig. 2). Interestingly, we also found reduced clot lysis during haemodilution with saline (fig. 2). This effect was most prominent at profound haemodilution, that is at 60% haemodilution with saline. Further studies are necessary to elucidate these findings.

It is difficult to extrapolate our findings to clinical practice. Intraoperative use of volume expanders such as albumin and gelatin may compromise blood coagulation to a lesser extent than hydroxyethyl starch. However, in the postoperative period, a period characterized by a hypercoagulable state, hydroxyethyl starch may be beneficial in reducing the risk of thrombosis.[27]

# Pharmacokinetics and pharmacokinetic–dynamic modelling of rocuronium in infants and children

J. M. K. H. Wierda, O. A. Meretoja, T. Taivainen and J. H. Proost

## Summary

We have determined the pharmacokinetics and pharmacokinetic–pharmacodynamic relationship of rocuronium in infants and children. We studied infants ($n$=5, 0.1–0.8 yr) and children ($n$=5, 2.3–8 yr), ASA II, in the ICU while undergoing artificial ventilation under i.v. anaesthesia with an arterial cannula *in situ* and the EMG of the adductor pollicis muscle was monitored. Rocuronium 0.06 (infants) and 0.09 (children) mg $kg^{-1}$ $min^{-1}$ was given i.v. over ±5 min until 85% neuromuscular block was obtained. Arterial blood samples were obtained over 240 min. Plasma concentrations were measured by HPLC. Pharmacokinetic–dynamic variables were calculated using the Sheiner model and the Hill equation. Statistical analysis was performed using the Mann–Whitney $U$ test ($P<0.05$). The mean administered dose was 0.32 (SD 0.08) mg $kg^{-1}$ and 0.4 (0.1) mg $kg^{-1}$ for infants and children, respectively. Infants differed from children in plasma clearance (4.2 (0.4) *vs* 6.7 (1.1) ml $min^{-1}$ $kg^{-1}$), distribution volume at steady state (231 (32) *vs* 165 (44) ml $kg^{-1}$), mean residence time (56 (10) *vs* 26 (9) min), concentration in the effect compartment at 50% block (1.2 (0.4) *vs* 1.7 (0.4) mg $litre^{-1}$) and the slope of the concentration–effect relationship (5.7 (1.3) *vs* 3.9 (0.5)). Calculated mean $ED_{90}$ values were 0.26 and 0.34 mg $kg^{-1}$ for infants and children, respectively. The time course of neuromuscular block after equipotent doses did not differ. (*Br. J. Anaesth.* 1997; **78**: 690–695).

Neuromuscular block, rocuronium. Infants. Children. Pharmacokinetics, rocuronium. Pharmacodynamics.

Rocuronium is an intermediate-acting non-depolarizing neuromuscular blocking agent that has a faster onset of action than other non-depolarizing neuromuscular blocking agents.[1] There are only two studies comparing the neuromuscular effects of rocuronium in infants with those in children.[2 3] These investigators obtained different results in that Woelfel and colleagues found that a fixed dose of rocuronium 0.6 mg $kg^{-1}$ had a longer neuromuscular blocking effect and a slower recovery in infants than in children.[2 4] Taivainen and colleagues administered individually determined $ED_{95}$ doses of rocuronium to infants, children and adults and found a similar duration of effect and recovery rate of neuromuscular function in all three age groups.[3] These apparently conflicting results may be explained by the pharmacokinetics of rocuronium. However, pharmacokinetic data currently available for rocuronium in infants are limited and cannot be used to explain the above pharmacodynamic differences.[5] We designed a study to analyse the pharmacokinetics and pharmacodynamic–kinetic relationship of rocuronium in infants and children in order to rationalize these apparently conflicting results in the literature and to contribute to the development of rational dose regimens.

## Patients and methods

After obtaining institutional Ethics Committee approval and parental written informed consent, we studied five infants and five children, ASA II, in the intensive care unit during stable recovery from elective tracheal or cardiovascular surgery, that is in a state of haemodynamic stability without supportive medication, normal peripheral (>32.5 °C) and core (>36.5 °C) temperatures, and normal values for blood chemistry, plasma proteins and packed cell volume. All patients were studied in the same intensive care unit. This site was chosen to guarantee stable cardiovascular and respiratory status of the patients, in the absence of surgical manipulations or bleeding during the study period, to allow an arterial cannula for arterial sampling to obtain reliable plasma concentrations for modelling. Surgical procedures in the patients are listed in table 1. Patients receiving medications or with diseases known to affect neuromuscular function, or patients with signs of hepatic or renal dysfunction were excluded.

Patients were routinely sedated and their lungs ventilated with the aid of i.v. bolus doses of

morphine and midazolam. Before calibration of the neuromuscular device patients received thiopentone 2–6 mg $kg^{-1}$ and alfentanil 20–80 μg $kg^{-1}$ to guarantee a sufficient level of anaesthesia during the period of neuromuscular block. Standard monitoring included ECG, pulse oximetry, continuous core and palmar skin temperature monitoring, and invasive arterial pressure measurement.

### NEUROMUSCULAR MONITORING AND SEQUENCE OF EVENTS

The arm opposite to the arm with the arterial cannula was used for neuromuscular measurements, that is adductor pollicis muscle electromyography (Relaxograph, Datex, Finland) after supramaximal train-of-four (TOF) stimulation (4 stimuli at a frequency of 2 Hz every 10 s). Surface stimulating electrodes were attached over the ulnar nerve on the wrist and recording electrodes over the adductor pollicis muscle, over the proximal volar surface of the index finger and at the radial side of the wrist distal to the stimulating electrodes.[6] Palmar skin temperature was obtained from the same hand. A stable calibration signal of the electromyographic trace was awaited before rocuronium was administered. Neuromuscular block was defined as percentage depression of the first EMG twitch response (T1) of the TOF compared with the baseline calibration response. After infusion of rocuronium, neuromuscular function was recorded in every patient until full spontaneous recovery of the EMG response had occurred. The stable twitch response after recovery (Tc) was used as a reference value to calculate EMG recovery data. The time of maximal neuromuscular block after rocuronium infusion and times from maximum block until recovery of T1 to 25% and 75% of Tc and to a train-of-four ratio (T4/T1) of 0.7 ($DUR_{0.7}$) were calculated. The recovery index ($RI_{25-75\%}$, time of T1 recovery from 25% to 75% of Tc) was derived from these data.

Rocuronium was administered by a continuous infusion joined by a needle to a rubber attachment of a steadily running central venous cannula. In five infants rocuronium, diluted in physiological saline to a concentration of 0.1 mg $ml^{-1}$, was infused end to side to a running peripheral venous cannula at a rate of 0.06 mg $kg^{-1}$ $min^{-1}$ until a decrease in twitch height of 85% was obtained. The infusion was then stopped to prevent occurrence of complete block. In five children, rocuronium, diluted in physiological saline to a concentration of 0.3 mg $ml^{-1}$, was infused via a peripheral venous cannula at a rate of 0.09 mg $kg^{-1}$ $min^{-1}$ also until 85% block was obtained.

Blood samples (0.5 ml) were obtained from an arterial cannula at the following times: one blank sample immediately before administration of rocuronium; five samples during onset of neuromuscular block at various degrees of block, that is at 1 and 2 min after the start of infusion and at approximately 20, 50, and 80% of block; one sample at maximum block; three samples at approximately 20%, 55% and 90% recovery of T1; and at 30, 45, 60, 90, 120, 180 and 240 min after disconnection of the infusion. Total sampling volume was restricted to less than 2% of the circulating blood volume of infants and to less than 1% of the circulating blood volume of children. Samples were stored in lithium heparinized tubes at room temperature until centrifugation, which took place within 4.5 h after the start of sampling. Plasma samples were stored at −20 °C after centrifugation. After completion of the study all samples were transported on dry ice to the analytical laboratory and stored at −18 °C until analysis.

### SAMPLE ANALYSIS

Concentrations of rocuronium (Org 9426) and its putative derivatives, 17-desacetyl-rocuronium (Org 9943) and 16-N-desallyl-rocuronium (Org 20860), were analysed by HPLC as described previously.[7] Using this method precision was almost independent of concentration and was 8%, 7% and 12% for rocuronium (10–20 000 ng $ml^{-1}$), Org 9943 (20–20 000 ng $ml^{-1}$) and Org 20860 (20–20 000 ng $ml^{-1}$), respectively. The accuracy for rocuronium, expressed as percentage recovered of the added amount, was 86%, 103%, 107% and 98% at concentrations of 10, 1000, 5000 and 10 000 ng $ml^{-1}$, respectively. At 20 and 200 ng $ml^{-1}$, accuracy was 92% and 106% for Org 9943, and 93% and 111% for Org 20860, respectively. The lower limit of quantification, defined as the lowest concentration that could be determined with a precision and accuracy greater than 15%, was 10, 20 and 20 ng $ml^{-1}$ for rocuronium, Org 9943 and Org 20860, respectively.

### PHARMACOKINETIC ANALYSIS

Pharmacokinetic analysis was based on iterative, non-linear, least-squares regression analysis by the computer program Multifit using the Marquardt minimizing algorithm.[8] Initial estimates were obtained by a stripping procedure. For each individual patient the parameters of a two- or three-exponential equation were fitted to the logarithm of the plasma concentration–time data pairs, assuming a constant relative error. The choice between a two- or three-compartment model was made on the $F$ test, accepting a more complex model as significantly better fitting if $P<0.05$. Relevant pharmacokinetic variables were calculated using standard equations, assuming the elimination to take place from the central compartment.[9]

### PHARMACOKINETIC–DYNAMIC MODELLING

The concentration–effect data were analysed using the computer program PkPdFit, the T1 data of the EMG and the values of the coefficients and exponents of a multiexponential equation, describing the concentration *vs* time data in plasma. For each individual patient the variables of the model of Sheiner and colleagues,[10] that is the rate constant between plasma and effect compartment ($k_{eo}$), the concentration in the effect compartment at 50% block ($EC_{50}$) and the sigmoidicity coefficient of the Hill equation ($\gamma$) were fitted to the effect using equal weight for each measurement. The fit was optimized with Simplex as the minimizing algorithm,[11] using sets of initial estimates obtained from previous fits. From these data individual $ED_{90}$ values, that is individual bolus doses resulting in 90% block, were derived.

### STATISTICAL ANALYSIS

All data are presented as mean (SD), [range] and {median} unless otherwise stated. Comparisons between data obtained in infants and children were made using the Mann–Whitney $U$ test. Pharmacokinetic–dynamic variables were related to age and weight by linear regression. $P<0.05$ was considered as an indicator of statistically significant difference.

The computer programs Multifit and PkPdFit were written by one of the authors (J. H. P.).

## Results

### PHARMACODYNAMICS

Patient data are shown in table 1. Tracheal resections had been performed 7 and 11 days before the study while other procedures had been finished 3–20 h before the start of the modelling study. All open heart surgical procedures were performed under normothermic conditions with a mean duration of extracorporeal perfusion of 33 (13) min. Mean time between the end of extracorporeal perfusion and initiation of this study was 7.9 h. The interval between the last dose of intraoperative neuromuscular blocking agent and the start of the modelling study was always more than 10 times the elimination half-life of the blocker given during operation. None of the patients had infusions of vasoactive drugs. Core and palmar skin temperatures did not differ between the groups during the study and averaged 36.9 (0.3) °C and 34.6 (1.5) °C, respectively. Mean duration of calibration was 16 (8) min. In infants, 0.32 (0.08) mg $kg^{-1}$ of rocuronium established 96.9 (2.9) % block in 6.6 (1.6) min. In children, these values were 0.4 (0.1) mg $kg^{-1}$, 96.5 (0.7)% and 5.9 (1.4) min, respectively (ns). $RI_{25-75\%}$ and $DUR_{0.7}$ were 9.1 (4.7) and 21.5 (11.8) min in infants, and 6.3 (0.7) and 14.0 (1.1) min in children, respectively (ns).

### PHARMACOKINETICS

The duration of rocuronium infusion was 5.3 (1.4) and 4.5 (1.1) min in infants and children, respectively. The dose administered was 1.21 (0.06) and 1.2 (0.05) times the individual $ED_{90}$ dose (calculated using individual PK/PD data) for infants and children, respectively. For all patients a three-compartment model fitted the plasma concentration *vs* time data significantly better than a two-compartment model. The residual coefficient of variation of the three-compartmental fits showed ranges and median values of [4.2–7.7%] {5.9%} and [7.7–20.9%] {13.1%} for infants and children, respectively. A representative example is presented in figure 1.

In infants, there was a significantly larger volume of distribution at steady state ($V^{ss}$), lower plasma clearance ($Cl_{pl}$), and consequently a longer mean residence time ($MRT_{iv}$) (table 2). The volume of the central compartment was similar in both age groups (table 2). There was a significant positive relationship for age (yr) and $Cl_{pl}$ (ml $min^{-1}$ $kg^{-1}$) ($Cl_{pl}$=0.403 age+4.25; $P$=0.005), whereas there were significant inverse relationships for age and $V^{ss}$ (ml $kg^{-1}$) ($V^{ss}$=−14.1 age+239; $P$=0.0019), and age and $MRT_{iv}$ (min) ($MRT_{iv}$=−5.20 age+55.8; $P$=0.0012). Similar relationships existed for body weight (kg) and $Cl_{pl}$ ($Cl_{pl}$=0.142 BW+3.65; $P$=0.019), body weight and $V^{ss}$ ($V^{ss}$=−5.30 BW+264; $P$=0.0041) and body weight and $MRT_{iv}$ ($MRT_{iv}$=−2.00 BW+65.7; $P$=0.0018). Potential metabolites of rocuronium in plasma were not detected.

### PHARMACOKINETIC–PHARMACODYNAMIC MODELLING

The goodness of the PK/PD fits ($r^2$) showed ranges and median values of [0.9912–0.9980] {0.9971} and [0.9925–0.9951] {0.9942} for infants and children, respectively. The ranges and median values of the residual SD, expressed as percentage twitch height depression, were [1.5–3.4] {1.9} and [2.2–2.9] {2.4} for infants and children, respectively. A representative example is presented in figure 2.

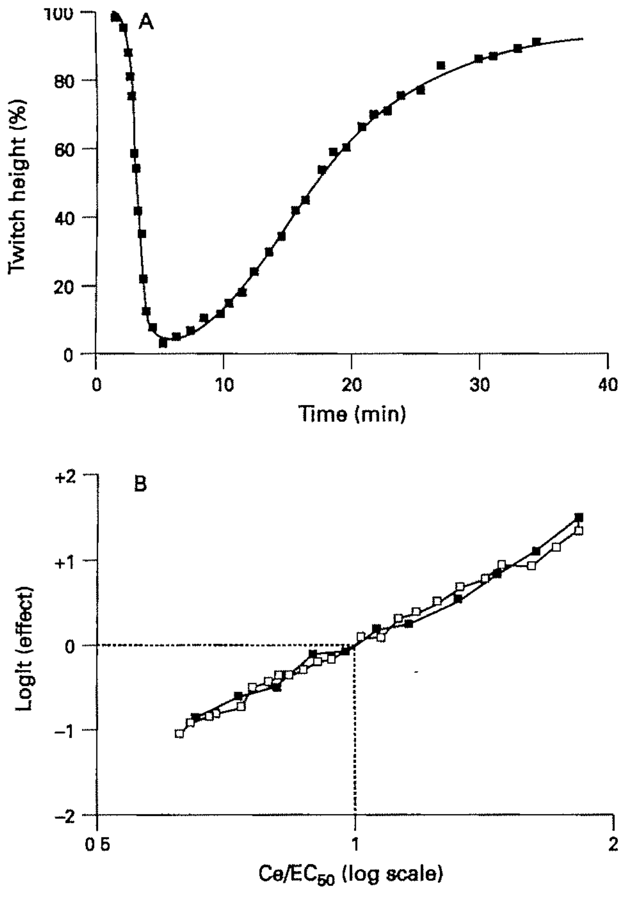

*Figure 2* Example of a pharmacodynamic–pharmacokinetic fit in an infant. A: Effects actually measured (■) with the curve fitted to them. B: Concentration–effect (logit scale) relationship in the effect compartment (■, onset □, offset).

The results of the modelling are presented in table 2. There was a significant inverse correlation for age and $\gamma$ ($\gamma$=−0.30 age+5.71; $P$=0.030), and for BW and $\gamma$ ($\gamma$=−0.13 BW−6.45; $P$=0.013).

## Discussion

This study was carried out under conditions that may differ from those in the operating theatre and in postoperative cardiac surgery patients. Although this may create limitations, we believe that the data may well be valid for developing dose regimens for general anaesthetic practice for the following reasons. (1) Our time course results were in agreement with those of other investigators, obtained in comparable age groups. (2) Our simulations with the PK/PD data predicted findings obtained previously for infants and children (see below). (3) Our patients were in a stable cardiovascular state without supportive medication and had normal values for blood chemistry, plasma proteins and packed cell volume. (4) The study was not commenced before at least 10 half-lives of the neuromuscular blocking agent used during operation had elapsed.

### PHARMACODYNAMICS

We found a similar time course of neuromuscular recovery after an $ED_{95}$ dose of rocuronium administered by infusion in infants and children. This result supports the study of Taivainen and colleagues.[3] Why, then, did Woelfel and colleagues find that after a constant dose of rocuronium 0.6 mg $kg^{-1}$, infants showed recovery times twice as long as those of children?[2 4] Our pharmacokinetic–pharmacodynamic data allowed us to model a pharmacokinetic–dynamic relationship in each individual patient for any dose of rocuronium. We simulated the time course of action of an individual $ED_{90}$ and of a fixed dose of 0.6 mg $kg^{-1}$ in infants and children (fig. 3).

Figure 3 demonstrates clearly how infants show a duration of effect of rocuronium twice as long as that of children after a constant dose of 0.6 mg $kg^{-1}$, despite similar time courses after an individual $ED_{90}$. If a dose of 0.6 mg $kg^{-1}$ is replaced by an intubating dose of twice the mean $ED_{90}$ values in infants and children, the difference becomes less pronounced but is still clinically relevant. $Dur_{25\%}$ of intubating doses (2×$ED_{90}$, i.e. 0.52 mg $kg^{-1}$ for infants and 0.67 mg

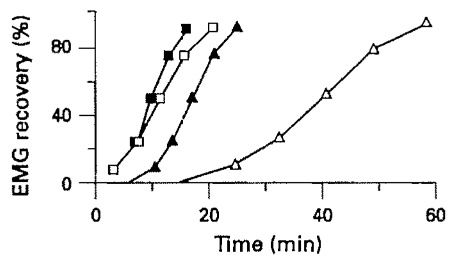

*Figure 3* Simulated time course of action in infants (open symbols) and children (closed symbols) of an $ED_{90}$ dose (□, ■) and of a dose of 0.6 mg $kg^{-1}$ (△, ▲) of rocuronium using the model according to Sheiner and colleagues[10] and the fitted values for the variables obtained in this study.

$kg^{-1}$ for children), calculated on the basis of the model, were 24 (8) and 14 (2) min and $RI_{25-75\%}$ 16 (7) and 8 (1) min for infants and children, respectively. Although our models in infants and children were based on data obtained in a limited number of patients under stable conditions in the postoperative period, their validity for prediction of the time course in these categories appears good because the outcome is supported in studies in which pharmacodynamic characteristics of different doses of rocuronium in paediatric patients have been evaluated.[2–4]

### PHARMACOKINETICS

We found several important pharmacokinetic differences between infants and children. $Cl_{pl}$ of rocuronium was significantly smaller while $V^{ss}$ was greater in infants than in children. This resulted in an $MRT_{iv}$ which was twice as long in infants as in children. These kinetic differences between infants and children resulted in protracted recovery of neuromuscular function in infants after a large bolus dose or repeated doses, as demonstrated by the modelling results shown in figure 3.

O'Kelly and co-workers also found positive correlations of weight-normalized clearance with age and weight.[5] For children aged 1–8 yr with a body weight of 10–25 kg, their results were in good agreement with our findings, as illustrated in figure 4.

Deviation of the results of our study in infants from those of O'Kelly and co-workers could reflect the method of data analysis used by O'Kelly and colleagues, who pooled data of children of various ages in their study. In contrast, Vuksanaj and Fisher reported that clearance (per kg body weight) in children aged 4–11 yr declined with age and body weight.[12] This apparent difference may be partly an artefact because of inclusion of extremely obese children, in particular in the age range 9–11 yr, resulting in an apparently small value for weight-normalized clearance. Over the range 5–8 yr, or 18–25 kg, which coincides with the age groups in the three studies, the differences between the studies are rather small (fig. 4). It is likely that weight-normalized clearance is maximal for children of 5–8 yr, or 18–25 kg, and declines with increasing age and body weight. This decline is likely to be related to declining body surface area/body weight ratio. Assuming a value of 4.0 ml $min^{-1}$ $kg^{-1}$ for clearance of a normal adult,[13] clearance normalized for body surface area is 150 ml $min^{-1}$ $m^{-2}$ for both adults and children.

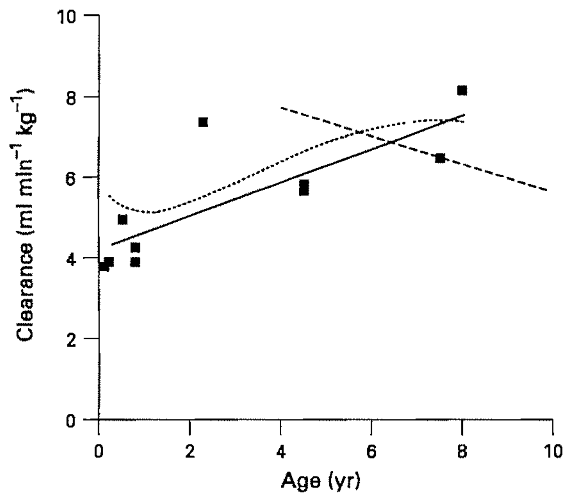

*Figure 4* Relationship between plasma clearance and age in infants and children (■). The solid line represents the regression line ($Cl_{pl}=0.40\times age+4.25$). The dotted line was calculated from the results of O'Kelly and colleagues (range 0.25–8 yr)[5] and the dashed line was calculated from the results of Vuksanaj and Fisher (range 4–11 yr).[12]

Figure 4 demonstrates that for children less than about 3 yr, clearance is lower than predicted from values of older children and adults. This lower clearance may reflect immaturity of the liver and kidneys, the main eliminating organs.[14]

We observed a negative correlation for weight-normalized volume of distribution at steady state and age and body weight. In contrast, O'Kelly and colleagues found that volume of distribution increased slightly with age and weight, [5] whereas Vuksanaj and Fisher did not find a significant trend in their study in children aged 4–11 yr.[12] One can only speculate on the reason for these differences. It is possible that the different methodologies in the three studies may have created the observed differences. Comparing our results with weight-normalized volume of distribution at steady state in adults (205 ml $kg^{-1}$),[13] it may be concluded that in children aged 4–8 yr, $V^{ss}$ is lower than in adults. In contrast, $V^{ss}$ in infants is higher than in adults and children. The distribution of quaternary compounds such as rocuronium and other neuromuscular blocking agents is limited to the extracellular fluid (ECF). During the first year of life, the volume of ECF decreases from 44% of body weight at birth to about 22% of body weight at 1 year, a value close to that in adults.[15] The higher percentage ECF predicts a higher $V^{ss}$ in infants compared with children and adults.

The larger plasma clearance and lower volume of distribution in children compared with both infants and adults resulted in a markedly lower mean residence time and a shorter duration of neuromuscular block. A short duration of action of an intubating dose of rocuronium has been observed in children compared with infants[2,16] and adults.[17]

Other non-depolarizing neuromuscular blocking agents do not seem to show similar correlations between pharmacokinetic variables and patient characteristics in children. All existing studies support the concept that the volume of distribution of a neuromuscular blocking agent is larger in infants than in children,[18–22] in accordance with the larger percentage of extracellular fluid. For plasma clearance the situation is different. Studies with atracurium revealed that plasma clearance is larger in infants than in children.[21,22] This may be explained by the organ-independent elimination rate in combination with the larger volume of distribution. A study with vecuronium showed similar plasma clearance in both age groups,[20] and studies with d-tubocurarine indicated that plasma clearance may be smaller in infants compared with children.[18,19] The latter finding may result from the relatively large contribution of renal clearance in elimination, compared with vecuronium.

### PHARMACOKINETIC–PHARMACODYNAMIC RELATIONSHIP

Our results showed that infants needed a lower concentration of rocuronium in the effect compartment than children in order to produce the same degree of neuromuscular block. This result corroborates data available for d-tubocurarine and vecuronium.[18–20] The lower effective concentrations in infants may be because of their potentially lower quantal content of acetylcholine, as shown in newborn rats, the larger incidence of single molecule block in infancy, and/or less protein binding as a result of low concentrations of plasma proteins in infants.[14 23 24] The slope of the concentration–response relationship based on the Hill equation was steeper in infants than in children. This finding supports the previous study of dose–response curves of rocuronium in infants, children and adults which showed the steepest slope in infants.[3] This steeper slope in infancy may be a unique characteristic of rocuronium as this phenomenon has not been seen with other neuromuscular blocking agents.[18 20 22]

# Use of inhaled nitric oxide in British intensive therapy units

B. H. CUTHBERTSON, S. STOTT AND N. R. WEBSTER

## Summary

The use of inhaled nitric oxide in the critically ill has increased significantly over the past few years but little published information exists on standards for current practice. Sixty-four intensive therapy units in the UK were surveyed by questionnaire from which 54 (84.4%) satisfactory replies were received. We present the survey results and put forward recommendations based on current literature and our own clinical experience for the safe use of inhaled nitric oxide. (*Br. J. Anaesth.* 1997; **78**: 696–700).

**Key words**
Gases non-anaesthetic. Pharmacology, nitric oxide. Anaesthesia, audit. Intensive care, audit.

The use of inhaled nitric oxide (NO) in intensive therapy units (ITU) in the UK has increased significantly over the past few years, despite the lack of evidence that it improves outcome.[1–4] There are currently no published recommendations for delivery, monitoring and scavenging of what is potentially a dangerous gas. In light of recent reports indicating the potential dangers of this therapy to both patients and staff,[5–8] we felt information was required on current British practice. In addition, we feel there is a need for recommendations regarding the safe administration and use of inhaled nitric oxide. We therefore sought to establish current practice of inhaled nitric oxide in the ITU and to compile recommendations for its safe use.

## Methods

Using the current Directory of Emergency and Special Care Units (1996), we phoned all adult, cardiac and paediatric ITU in the UK with more than four beds and spoke to either medical or senior nursing staff. Special care baby units were excluded. A postal questionnaire was sent to all units that used inhaled nitric oxide therapy (appendix 1). We asked about indications for its use and currently used methods of delivery, monitoring and scavenging in individual units. Units were also asked about the minimum level of monitoring that they considered satisfactory for its safe use.

## Results

Sixty-four units were identified and completed replies were received from 54 (84.4%) after two mailings. Of these, 35 were adult units with 10 performing cardiac surgery, another eight were mixed adult and paediatric ITU and 11 were paediatric ITU. Within these units there was a mean of 8.5 (range 2–22) general beds, 8.0 (1–22) paediatric beds and 8.0 (3–12) cardiac beds.

### INDICATIONS

The most frequent indications for the use of inhaled nitric oxide are shown in table 1. Other less frequent indications for its use included weaning from extracorporeal membrane oxygenation (two units), ventricular off-loading in cardiac failure (two) and bronchiolitis (one). Using the American–European consensus conference definitions (appendix 2),[9] we were able to establish the disease severity for which units introduce inhaled nitric oxide therapy into clinical management of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) (table 2). Of the 54 units which replied, the mean period that these units had used inhaled nitric oxide was 2.1 (0.1–6.0) yr. Twenty-seven units (50.0%) were carrying out research into some aspect of inhaled nitric oxide therapy and five (9.3%) used inhaled nitric oxide only as part of a study.

*Table 1* Indications for use of inhaled nitric oxide therapy (%). ALI=acute lung injury, ARDS=acute resiratory distress syndrome

| Indications | Incidence (%) |
|---|---|
| ALI/ARDS | 91 |
| Pulmonary hypertension | 70 |
| Paediatric cardiac surgery | 24 |
| Cardiac surgery | 18 |
| Cardiac transplantation | 9 |
| Other | 17 |

| Severity | Incidence (%) |
|---|---|
| ALI | 26 |
| ARDS | 12 |
| SRF | 46 |
| Other | 16 |

DELIVERY AND MONITORING

Ten (18.5%) units used an inspiratory injection system which injects nitric oxide into the inspiratory limb only during the inspiratory phase of the ventilator cycle; 52 (96.3%) used a continuous flow system and eight (14.8%) used both systems. To monitor delivery of inhaled nitric oxide, eight (15.9%) units used only chemiluminescent monitoring, 48 (90.6%) units used an electrochemical monitor, and eight (15.1%) units used both systems. Two (3.8%) units monitored expired nitrogen dioxide concentrations while six (11.3%) units measured environmental nitrogen dioxide. Two (3.8%) units did not monitor the concentration of inhaled nitric oxide.

Regarding minimum monitoring standards for the safe use of inhaled nitric oxide, eight (15.1%) units believed that inspiratory chemiluminescence monitoring of nitric oxide and nitrogen dioxide was required, whereas 45 (84.9%) thought that inspiratory electrochemical monitoring of nitric oxide and nitrogen dioxide was adequate. In addition to inspiratory monitoring, 22 (41.5%) units stated that expiratory monitoring should also be used. Three (5.9%) of these stated that a chemiluminescence analyser was necessary and 19 (35.8%) thought that electrochemical monitoring was sufficient. Only nine (16.9%) units felt that environmental nitrogen dioxide monitoring was necessary. Comparison between actual use of monitoring and what the surveyed units stated to be minimum monitoring standards is shown in table 3. Methaemoglobin concentrations were measured daily in 27 (54%) units; in 16 (32.0%) it was measured with every blood-gas analysis but in seven (14.0%) units it was not measured. Four (7.6%) units said that although they measured methaemoglobin concentrations they did not feel it was necessary.

*Table 3* Current use of monitoring compared with surveyed units stated minimum monitoring standards

| | Current monitoring (%) | Stated minimum standard (%) |
|---|---|---|
| Inspiratory chemiluminescence monitoring | 16 | 15 |
| Inspiratory electrochemical monitoring | 91 | 85 |
| Expiratory monitoring | 4 | 42 |
| Environmental monitoring | 11 | 17 |

SCAVENGING

Table 4 shows the different methods of scavenging. Of the units using filtration systems, three (5.8%) units used the ABEK HgCONO-P3 filter, five (9.6%) units used charcoal absorbers and four (7.7%) units used soda lime.

*Table 4* Use of scavenging systems with inhaled nitric oxide therapy

| Type of scavenging used | Incidence (%) |
|---|---|
| Passive | 19 |
| Filtration | 23 |
| Active | 23 |
| None | 40 |

## Discussion

The potential benefits of nitric oxide are attractive to improve oxygenation and reduce pulmonary artery pressures in ARDS and act as a pulmonary artery vasodilator in pulmonary artery hypertension without systemic effects. As yet, these benefits are not proved in terms of patient outcome and thus therapy should still be thought of as experimental. We found that 50% of the units currently using inhaled nitric oxide were carrying out research in this area and thus nitric oxide is being used widely in research designs. Only 9.4% of responding units were using it solely for research purposes. Until the risk/benefit ratio has been established it would seem logical to use inhaled nitric oxide therapy in more severely ill critical care patients. No evidence is yet available to allow recommendations to be made for the introduction of inhaled nitric oxide. Our opinion is that in ARDS, ventilation should be optimized with an arbitrary partial pressure of arterial oxygen to fractional inspired oxygen concentration ratio ($Pa_{O_2}:FI_{O_2}$) of less than 14 kPa (106 mm Hg) before introduction of inhaled nitric oxide for clinical purposes.

DELIVERY

There are essentially two ways to deliver inhaled nitric oxide, either continuously or by intermittent flow. The gold standard for nitric oxide delivery is a Servo controlled inspiratory injection device such as the NODOMO system (Dräger Medical UK, Hemel Hemstead, Herts, UK) which allows injection of nitric oxide into the inspiratory limb of the system during inspiration only. This technique reduces the bolus effect seen with continuous flow systems and reduces nitrogen dioxide formation because of decreased nitric oxide and oxygen mixing time.[9 10] The continuous flow system uses a calibrated flowmeter delivering a continuous flow of nitric oxide–nitrogen 10–800 ml min$^{-1}$ throughout the respiratory cycle.[9] Medical quality nitric oxide–nitrogen is available in cylinders for direct patient use or can be delivered through stainless steel medical gas piping. Medical quality nitric oxide–nitrogen gas cylinders with a stainless steel pressure regulator, connectors and calibrated stainless steel flowmeter needle valves are the minimum required for the safe delivery of inhaled nitric oxide. Polytetrafluroethylene (PTFE) tubing for the delivery of inhaled nitric oxide is safe (personal communication, Nigel Wadsworth, BOC Special Gases, Guildford, Surrey). Cylinders of nitric oxide–nitrogen are available in 10- and 40-litre sizes and must be secured in the ITU so as to avoid injury. Methods of delivery for inhaled nitric oxide in the UK vary but the majority (96.3%) use nitric oxide cylinders and a continuous flow system. Some units did not monitor the delivery of nitric oxide; we would strongly discourage this practice.

### MONITORING

Nitric oxide in gas mixtures can be measured either with chemiluminescence or electrochemical analysers. Electrochemical analysers monitor both nitric oxide and nitrogen dioxide concentrations to an accuracy of at least 1 part per million (ppm) while chemiluminescence analysers monitor nitric oxide, nitrogen dioxide and other higher oxides of nitrogen to an accuracy of a few parts per billion. When placed at the distal end of the inspiratory limb, nitric oxide and nitrogen dioxide monitors provide information on the delivered dose of nitric oxide to the patient and information on the formation and delivery of the potentially toxic nitrogen dioxide. Few clinical indications require delivery of greater than 80 ppm of inhaled nitric oxide and this should be regarded as a maximum dose,[2 3 10 12] but it should be noted that the Control of Substances Hazardous to Health (COSHH) guidelines for inspired nitric oxide concentrations are 25 ppm over an 8-h time-weighted average (TWA) and 35 ppm over a 15-min TWA. Maximum nitrogen dioxide concentrations should be less than 3 ppm over an 8-h TWA and 5 ppm over a 15-min TWA.[12] There is evidence that concentrations as low as 5 ppm of nitrogen dioxide cause surfactant damage in rats.[13 14] Nitrogen dioxide monitoring in the expiratory limb of the system provides some information on the amount of nitrogen dioxide being exhausted from the system but this does not reflect environmental nitrogen dioxide concentrations.[15–17] We recommend that inspiratory electrochemical or chemiluminescence monitoring of nitric oxide and nitrogen dioxide is the minimum requirement. Expiratory monitoring of nitrogen dioxide does not provide any useful information on atmospheric nitrogen dioxide concentrations and thus we do not feel its measurement is routinely required.

Environmental nitric oxide and nitrogen dioxide monitoring in the ITU can be performed using chemiluminescence or electrochemical analysers at the patient bedside. Environmental nitric oxide concentrations should not exceed the COSHH guidelines, but concentrations of 1 ppm of nitric oxide are the highest recorded in a clinical environment during the use of inhaled NO.[10 15] In light of the current published data, environmental nitric oxide and nitrogen dioxide monitoring is not routinely required.

The reaction of nitric oxide with haemoglobin produces the compound methaemoglobin. Doses of nitric oxide far greater than those used clinically do not cause significant methaemoglobinaemia in adults.[18] To date there are only two case reports of significant methaemoglobinaemia during inhaled nitric oxide therapy. Both were in babies and in one case there was an overdose of nitric oxide.[19 20] Inhaled nitric oxide has now been used in many thousands of patients without further reports of methaemoglobinaemia. We suggest that methaemoglobin measurements may be unnecessary, but until further evidence is available they should be measured daily.

A surprisingly high percentage (41.5%) of respondents thought that expired nitrogen dioxide monitoring was a minimum requirement but there is no current evidence to support this practice. Otherwise, the minimum monitoring standards from the surveyed units broadly agreed with our recommendations for inspiratory nitric oxide and nitrogen dioxide and daily methaemoglobin measurement being the minimum requirement. Although we do not feel that exhaled or environmental nitrogen dioxide measurements are required, we would not discourage this safety orientated approach. Environmental electrochemical nitrogen dioxide monitors are now readily available at an affordable price.

### SCAVENGING

Scavenging can be used both in the inspiratory limb of the system to scavenge inspired nitrogen dioxide or on the expiratory limb to scavenge expired nitric oxide and nitrogen dioxide. Active scavenging systems would be the gold standard for nitric oxide and nitrogen dioxide scavenging, but are expensive and are not commonly available in the ITU. Active scavenging can also affect the performance of the expiratory valve of the ventilator. Because of the high moisture content of both inspired and expired gases, passive scavenging, which usually involves a length of hose being placed out of a window, is often associated with excess moisture collection in the tubing. Expiratory scavenging of nitric oxide or nitrogen dioxide with soda lime has been reported to be ineffective and although soda lime containing potassium permanganate indicator has been shown to scavenge inspired nitric oxide and nitrogen dioxide, this was probably because of the reaction of the indictor and not the soda lime.[21 22] Two stage permanganate and charcoal filtration devices are also available but there is no clinical evidence regarding efficiency. The lack of evidence for effectiveness of soda lime in expiratory scavenging implies that we are unable to recommend its clinical use at this time. Charcoal type absorbers are ineffective absorbers of nitric oxide or nitrogen dioxide.[21] The ABEK HgCONO-P3 filter (Dräger Industrial Ltd., Hemel Hempstead, Herts, UK) which is used industrially appears to scavenge nitric oxide and nitrogen dioxide effectively.[21]

More than half (59.6%) of responding units used some type of scavenging system. Health Technical Memorandum 2025 states that in units with adequate ventilation in clinical areas (10–12 air changes per hour), scavenging of nitric oxide or nitrogen dioxide is not necessary but recommends scavenging in units that do not reach this standard.[21 23] Expiratory scavenging using the ABEK HgCONO-P3 filter, active or passive scavenging are appropriate in units that do not meet the above guidelines. We would not discourage the practice of scavenging exhaled nitric oxide and nitrogen dioxide and would recommend scavenging in poorly ventilated units. It should be noted that there is little evidence to support the use of soda lime or charcoal absorbers in the scavenging of exhaled nitric oxide and nitrogen dioxide.

In summary, inhaled nitric oxide is a new form of therapy in the ITU. The use of this potentially toxic compound should be supervised closely by experienced clinicians and its delivery and monitoring standardized to acceptable minimum levels. At present there is wide variety in the standards of clinical practice for using inhaled nitric oxide in the UK. We have put forward recommendations (appendix 3) for its use with the belief that this will promote discussion and research into nitric oxide therapy and with the hope that national guidelines may soon become available.

## Appendix 1

SURVEY OF THE USE OF INHALED NITRIC OXIDE IN THE ITU

Unit number ________________

Dear Colleague

We believe that your unit uses inhaled nitric oxide therapy. As you are probably aware there has been concern stated by the CSM on the use of inhaled NO in clinical practice. We are conducting a postal survey of all the units in the UK that use inhaled NO. We would appreciate if you could complete this short questionnaire and return it to us in the enclosed STA as soon as it is convenient.

Thank you for your help.

Brian H Cuthbertson and Steve Stott, Intensive Care Unit, Aberdeen Royal Infirmary, Aberdeen.

**A.**

Name of unit ________________

Name of person filling in questionnaire ________________

Grade ________________

Bed number:- total___ general___ paediatric___ cardiac___

**B.** How long have you used it:- ____ years____ months

What indications do you use inhaled NO for in your hospital:-

a. ALI/ARDS ☐
b. Secondary pulmonary hypertension ☐
c. Pulmonary vasodilator during adult cardiac surgery ☐
d. Cardiac transplant surgery ☐
e. Paediatric cardiac surgery ☐
f. RDS of the newborn ☐
g. Others -please state ________________

If you use inhaled NO for ALI/ARDS, what criteria do you use for its use? (American–European consensus conference definitions).

a. Consensus conference definition for ALI ☐
($Pa_{O_2}/FI_{O_2}$ ratio <300 mm Hg, infiltrates on CXR, PCWP <18 mm Hg)

b. Consensus conference definition for ARDS ☐
($Pa_{O_2}/FI_{O_2}$ ratio <200 mm Hg, infiltrates on CXR, PCWP < 18 mm Hg)

c. Severe respiratory failure (ECMO) criteria ☐
($Pa_{O_2}$ <8 kPa on $FI_{O_2}$ 1.0 for >8 h)

d. Other (please state) ________________

Are you undertaking research in the subject of inhaled NO:- Yes / No

Are you using inhaled NO only as part of a trial:- Yes / No

What equipment do you use for *administration* of inhaled NO ________________

What equipment do you use for *measurement* of inhaled NO levels ________________

What monitoring do you feel is the minimum necessary for the safe use of inhaled NO:-

a. Inspired NO and $NO_2$ levels:-
  chemiluminescent monitor ☐
  electrochemical monitor ☐
b. Expired NO and $NO_2$ levels -
  chemiluminescent monitor ☐
  electrochemical monitor ☐
c. Methaemoglobin levels:- Daily ☐ Every gas ☐ Not required ☐

# Comparison of the effects of ketamine–midazolam with those of fentanyl–midazolam on cortical somatosensory evoked potentials during major spine surgery†

O. LANGERON, F. LILLE, O. ZERHOUNI, G. ORLIAGUET, G. SAILLANT, B. RIOU AND P. CORIAT

## Summary

Cortical somatosensory evoked potentials (CSEP) allow monitoring of spinal cord function during surgery. Ketamine has been shown to enhance CSEP amplitude, but there is no previous study comparing its effects with those of other anaesthetic regimens. Therefore, we have compared the effects of ketamine with those of fentanyl, both combined with midazolam, on CSEP monitoring during major spine surgery. Twenty patients with normal preoperative CSEP were allocated randomly to a ketamine or fentanyl group. Anaesthesia was induced with ketamine 3 mg kg$^{-1}$ or fentanyl 6 µg kg$^{-1}$ i.v., and midazolam 0.3 mg kg$^{-1}$ i.v in both groups, and maintained with continuous i.v infusion of ketamine 2 mg kg$^{-1}$ h$^{-1}$ or fentanyl 3 µg kg$^{-1}$ h$^{-1}$, combined in both groups with midazolam 0.15 mg kg$^{-1}$ h$^{-1}$ and 60% nitrous oxide in oxygen. CSEP were elicited by tibial posterior nerve stimulation and measured P1 and N1 latencies, and P1-N1 amplitude. CSEP were recorded before and after induction, at 15 min, 1 and 2 h after induction, during skin closure and after removal of nitrous oxide. Both groups were comparable in characteristics, duration of surgery, mean arterial pressure and temperature. CSEP latencies were not significantly affected in either group. CSEP amplitude decreased significantly over time in the fentanyl group (from mean 2.02 (SEM 0.41) to 0.95 (0.17) µV, $P<0.05$), but not in the ketamine group (from 1.33 (0.36) to 1.05 (0.31) µV, ns). Nevertheless, we did not observe any significant differences in amplitudes or latencies between the two groups. The delay in obtaining the first voluntary postoperative motor response was significantly greater in the ketamine group (170 (54) *vs* 55 (17) min, $P<0.01$). Both ketamine and fentanyl allowed us to obtain reliable CSEP during major spine surgery, and there were no significant difference between these two anaesthetic regimens for CSEP monitoring, but a longer delay for voluntary postoperative motor assessment was observed in the ketamine group. (*Br. J. Anaesth.* 1997; **78**: 701–706).

**Key words**
Brain, evoked potentials. Anaesthetics i.v., ketamine. Analgesics opioid, fentanyl. Hypnotics benzodiazepine, midazolam. Surgery, spinal.

Cortical somatosensory evoked potentials (CSEP) assess neural transmission in afferent spinal cord pathways and are used to monitor spinal cord function during spine surgery to prevent neurological injury.[1,2] However, changes in CSEP may result from surgical stimulation,[3,4] anaesthetic agents[5–8] or haemodynamic instability.[1,9] Consequently, to improve CSEP recording and increase their reliability, the anaesthetic technique should minimize its effects on amplitudes and latencies of CSEP, and provide haemodynamic stability.

Previous studies have reported that fentanyl[3,5,7,10] and midazolam[7] induce modest alterations in CSEP amplitudes and latencies enabling appropriate monitoring of CSEP signals. Moreover, the combination of fentanyl and midazolam provides haemodynamic stability. Ketamine has been shown to enhance CSEP amplitude and has therefore been suggested as a useful anaesthetic agent when CSEP are required, enabling more reliable intraoperative spinal cord function monitoring.[11] However, this study was not performed during spine surgery, did not assess the effects of ketamine over a long period and did not compare ketamine with another anaesthetic agent. Thus our prospective, randomized study was undertaken to compare the effects of ketamine–midazolam with fentanyl–midazolam anaesthesia on CSEP monitoring during major spine surgery.

## Patients and methods

After obtaining approval from the local Ethics Committee and informed consent, we studied 20 consecutive ASA I–II patients undergoing major spine surgery (scoliosis or spinal fusion). Patients

with abnormal preoperative CSEP were excluded; additional criteria for exclusion were hypertension, coronary artery disease, psychiatric disorders and ASA III or IV status.

### ANAESTHESIA TECHNIQUE

Patients received hydroxyzine 1–1.5 mg kg$^{-1}$ orally 90 min before surgery. Using a random number table, patients were allocated to a ketamine or fentanyl group. Anaesthesia was induced with ketamine 3 mg kg$^{-1}$ or fentanyl 6 μg kg$^{-1}$ i.v., combined with midazolam 0.3 mg kg$^{-1}$ i.v in both groups. Neuromuscular block for tracheal intubation was produced with vecuronium 0.1 mg kg$^{-1}$ i.v. Anaesthesia was maintained with continuous i.v. infusion of ketamine 2 mg kg$^{-1}$ h$^{-1}$ or fentanyl 3 μg kg$^{-1}$ h$^{-1}$, combined with midazolam 0.15 mg kg$^{-1}$ h$^{-1}$ and 60% nitrous oxide in oxygen in both groups. After skin closure, nitrous oxide was first removed and after the last CSEP measurement the infusions were discontinued.

Throughout the study the lungs were ventilated mechanically and minute ventilation was adjusted to maintain end-tidal carbon dioxide tension ($E'_{CO_2}$) at 4.0–4.8 kPa. Oesophageal temperature was monitored, and hypothermia was prevented using a heating blanket and perfusion warming. Haemodynamic measurements were obtained via an indwelling radial artery catheter connected to a haemodynamic monitor (HP 78354, Hewlett-Packard, Andover, MA, USA). When required, an i.v. bolus of nicardipine 2 mg (Loxen, Sandoz) was administered to maintain mean arterial pressure (MAP) at 60–80 mm Hg to decrease intraoperative bleeding. Haemoglobin concentration was measured during operation using an infrared monitor (HemoCue, Angelholm, Sweden) and was maintained greater than 8 g dl$^{-1}$ using autologous and homologous blood transfusion, as available.

### CSEP RECORDING

CSEP were recorded with a Nicolet compact IV (Nicolet Biomedical Instruments, Madison, WI, USA) and were elicited by alternate right and left tibial posterior nerve stimulation with subdermal needle electrodes placed on the ankle (frequency 4.3 Hz, duration 150 ms, intensity twice the motor threshold). As regional hypothermia could affect CSEP,[12] we paid careful attention to covering the lower limbs with a heating blanket. CSEP were recorded simultaneously with transcutaneous scalp Ag–AgCl electrodes (impedance<2 kΩ) located in the medio-central and medio-frontal positions ($C_Z$-$F_Z$ in the International 10-20 System).[1] To obtain a better CSEP signal, 500 stimulations were cumulated and averaged every 2 min, using bandpass filters of 10 and 1000 Hz and recorded over a 100-ms time base. At each sample period, CSEP measurements were obtained by averaging duplicate tracings. During diathermy, CSEP acquisition was halted automatically. According to the nomenclature of the cortical peaks of tibial nerve evoked potentials described by Nuwer[13] and Stöhr,[14] positive waves of the CSEP are represented by downward deflections and labelled P (fig. 1). In the same way, negative waves of the CSEP are represented by upward deflections and labelled N (fig. 1). Latencies were measured regarding positivity at approximately 40 ms (P1) and negativity at approximately 50 ms (N1) of the primary cortical peaks from the time of stimulus. Amplitude (A) was measured from peak to peak of these two deflections (fig. 1). CSEP monitoring was recorded continuously by a trained neurophysiologist who was unaware of the anaesthesia technique used. Intraoperative abnormalities of CSEP were defined as an increase in latency (P1 or N1) of at least 10% of previous values (throughout two acquisition periods, 4 min) and a decrease in amplitude of at least 50% of previous values, as reported previously.[1 2 6] According to our routine procedure and as recommended previously,[2] a "wake-up" test[15] was required if such abnormalities occurred during a high-risk period of surgery.

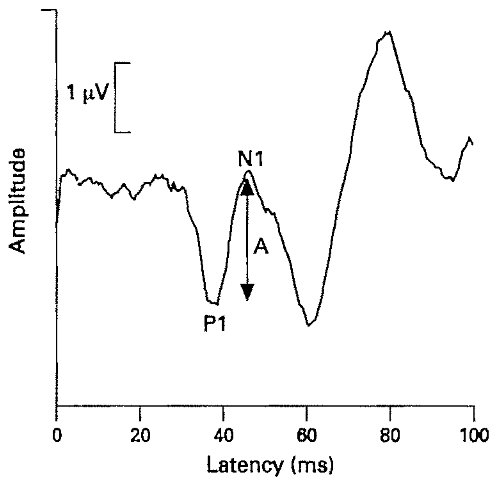

*Figure 1* Typical tracing of cortical somatosensory evoked potentials after tibial posterior stimulation. P1 = first positive deflection occuring at approximately 40 ms from the time of stimulus, N1 = first negative deflection occuring at approximately 50 ms from the time of stimulus. Amplitude (A) was measured from peak to peak of these two deflections.

### MEASUREMENTS

The following variables were measured simultaneously while patients were awake (control period), at the end of induction, 15 min, 1 and 2 h after induction, during skin closure and after removal of nitrous oxide (expired concentration ($E'_{N_2O}$) less than 10%) : heart rate (HR), MAP, $E'_{CO_2}$, $E'_{N_2O}$, oesophageal temperature and CSEP. Before and after induction, at the end of surgery and in the recovery room, arterial blood was obtained to measure partial pressure of oxygen ($Pa_{O_2}$) (BGElectrolytes Apparatus, Instrumentation Laboratory, Milano, Italy) and haemoglobin concentration (Cobas Argo, Apparatus, Roche, Basle, Switzerland). We also recorded the amount of crystalloids, colloids and blood administered during operation, duration of anaesthesia and surgery, and delay between the end of anaesthesia and the first voluntary postoperative motor response of the lower limbs. To obtain a reliable voluntary motor response of the lower limbs, this test was explained to each patient during the preoperative visit, and the postoperative assessment was performed every 15 min in the recovery room by a physician who was unaware of the anaesthesia technique.

### STATISTICAL ANALYSIS

Data are expressed as mean (SEM). Comparisons of two means and two percentages were performed using the Student's *t* test and Fisher's exact method, respectively. Comparison of several means was performed using repeated-measure analysis of variance and Newman–Keuls test. All *P* values were two-tailed and $P<0.05$ was considered significant. Statistical analysis was performed on a computer using PCSM software (Deltasoft, Meylan, France).

## Results

CSEP recording was available and satisfactorily analysed in all patients throughout the study. We did not have to perform a wake-up test, and no neurological complications occurred during or after surgery. We did not observe any undesirable psychomimetic side effects related to ketamine. There were no significant differences between the two groups in age, ASA status, body weight, duration of anaesthesia or surgery, total dose of nicardipine, intraoperative fluids or blood transfusion (table 1). HR was significantly greater in the ketamine group, but MAP, temperature, $E'_{CO_2}$, $Pa_{O_2}$ and haemoglobin concentration were not significantly different between the two groups (table 2).

CSEP amplitude decreased significantly from induction until the end of surgery in comparison with control values in the fentanyl group (from 2.02 (0.41) to 0.95 (0.17) µV, $P<0.05$), but not in the ketamine group (from 1.33 (0.36) to 1.05 (0.31) µV, ns). However, there were no significant differences between the two groups (fig. 2). In both groups, we observed no significant increases in CSEP amplitude at the end of surgery after removal of nitrous oxide and there were no significant differences between groups (fig. 2).

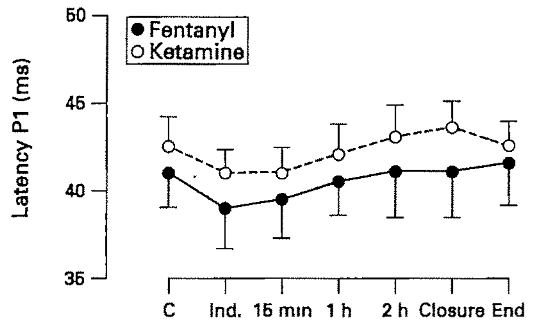

*Figure 3* Comparison of P1 latency of cortical somatosensory evoked potentials in the ketamine ($n$=10) and fentanyl ($n$=10) groups when awake (control (C)), immediately after induction of anaesthesia (Ind.), at 15 min, 1 and 2 h of anaesthesia, during skin closure (Closure) and at the end of anaesthesia with removal of nitrous oxide (i.e end-tidal nitrous oxide <10%) (End). Data are mean (SEM). No significant differences between groups.

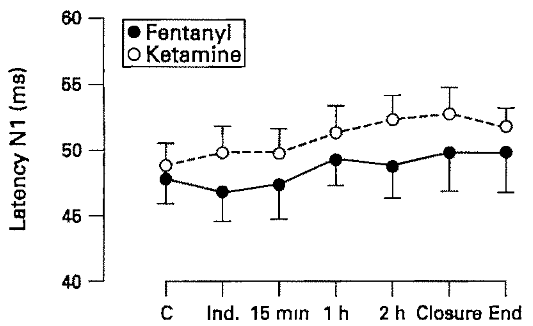

*Figure 4* Comparison of N1 latency of cortical somatosensory evoked potentials in the ketamine ($n$=10) and fentanyl ($n$=10) groups when awake (control (C)), immediately after induction of anaesthesia (Ind.), at 15 min, 1 and 2 h of anaesthesia, during skin closure (Closure) and at the end of anaesthesia with removal of nitrous oxide (i.e end-tidal nitrous oxide <10%) (End). Data are mean (SEM). No significant differences between groups.

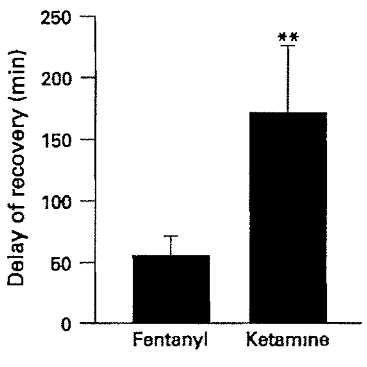

*Figure 5* Delay of recovery assessed by the first motor response obtained during the postoperative period in the ketamine ($n$=10) and fentanyl ($n$=10) groups. Data are mean (SEM). $^{**}P<0.01$ *vs* fentanyl group.

Latencies of P1 (fig. 3) and N1 (fig. 4) remained unchanged in each group throughout the study, including during removal of nitrous oxide. There were no significant differences in latencies between the two groups (figs 3, 4).

We observed a significantly longer delay of recovery, assessed by the first voluntary motor response, in the ketamine group compared with the fentanyl group (fig. 5).

## Discussion

We found that both ketamine–midazolam and fentanyl–midazolam anaesthesia, with 60% nitrous oxide in oxygen, enabled us to obtain satisfactory CSEP recordings, and we did not observe any significant differences in latencies and amplitudes of CSEP between the two groups. In contrast, recovery was delayed significantly in the ketamine group.

During spine surgery, CSEP monitoring provides sensitive information on spinal cord dysfunction caused by mechanical spinal cord injury, ischaemia, or both.[1 2 9] In a large multicentre survey, including 51 263 procedures for major spine surgery, Nuwer and colleagues[2] reported that neurological deficits occurred in only 0.55% of patients when CSEP monitoring was performed. To increase the reliability of CSEP recording and monitoring, several independent technical factors should be controlled to decrease false positive and negative rates of spinal injury. First, experience in CSEP monitoring is an important factor, as reported previously.[1 2 16] In our study, CSEP monitoring was performed by the same neurophysiologist (F. L.) highly trained in intraoperative CSEP monitoring.[17 18] Second, the early cortical components, P1 and N1, are considered the most reliable waveforms for CSEP recording[1 19] because their amplitude is greater than that of other peaks and because they exhibit lower variability.[6] Indeed, P1 and N1 components usually exhibit variability less than 30% in amplitude and 1.0 ms in latency.[16] Consequently, in our study, P1 and N1 were analysed to obtain a better signal-to-noise ratio and to increase the reliability of our CSEP recordings. Third, factors other than the anaesthesia technique can affect CSEP recording. These factors are related to spinal cord ischaemia, profound and sustained systemic hypotension,[9 20] severe hypoxia[21] and low packed cell volume with hypovolaemic status.[1 20] In contrast, isovolaemic haemodilution in subjects with normal CSEP, as in our study, does not affect CSEP monitoring.[22] Impairment of CSEP monitoring may be related (mainly latencies rather than amplitudes) to hypothermia in the 25–35 °C temperature range,[23–25] hypocapnia[25 26] and hypercapnia.[25] We controlled all of these factors during surgery, including regional limb hypothermia. However, we recorded oesophageal temperature which correlates better with CSEP changes than lower limb muscle temperature.[24] Thus MAP, oesophageal temperature, $E'_{CO_2}$, $Pa_{O_2}$ and haemoglobin concentration were maintained within values which enabled CSEP to be monitored satisfactorily throughout the study (table 2). Moreover, there were no significant differences between the two groups for each of these variables (table 2). Lastly, neuromuscular block was produced by vecuronium for tracheal intubation but was not maintained during the study. Neuromuscular block has not been shown to alter CSEP recording.[27]

CSEP may be affected by volatile or i.v. anaesthetics,[1 5–8] and by their mode of administration (bolus *vs* continuous).[1 7 10] To improve CSEP recording and signal-to-noise ratio, some authors have suggested previously that ketamine be used as a general anaesthetic to increase cortical amplitudes of CSEP produced by peripheral nerve stimulation.[11] In contrast with previous observations, CSEP amplitude in the ketamine group was not increased significantly in our study. This difference may be explained easily. In our study, CSEP monitoring was performed throughout surgery over a long period (more than 2 h) and not only during the first 60 min after induction. As reported previouly,[28] the time course of anaesthetic effects on CSEP may be prolonged and complex, and to avoid confusing transient CSEP changes with sustained changes, a prolonged study is required. Examination of the results from Schubert, Licina and Lineberry[11] shows that the increase in CSEP amplitude was significant only during the first 30 min, immediately after bolus injection of ketamine, and was no longer significant 60 min later in comparison with pre-induction values, with or without exposure to nitrous oxide. To avoid transient CSEP changes, we performed continuous administration of i.v. anaesthetics. Moreover, our results are in accordance with a recent study in humans[29] which reported that the amplitude of mid-latency auditory evoked potentials is maintained, and not increased, during ketamine anaesthesia, compared with pre-induction values. It should also be pointed out that CSEP were recorded from the upper and not from the lower limbs in the study of Schubert, Licina and Lineberry.[11] Moreover, as in the studies carried out by Schubert, Licina and Lineberry[11] and Schwender and colleagues,[29] we did not observe any significant changes in the latencies of P1 and N1 with ketamine, and no significant differences were noted for latencies between the two groups. In summary, there were no significant differences between ketamine–midazolam and fentanyl–midazolam anaesthesia for CSEP variables throughout the study.

The only significant difference between the two groups was a greater delay in obtaining the first voluntary motor response in the recovery room. This suggests that the diagnosis of potential spinal cord dysfunction in the immediate postoperative period should have been delayed. Indeed, rapid postoperative assessment of spinal cord function is important to detect: (1) spinal cord injury limited to motor pathways, thus not detected by CSEP; (2) delayed consequences of intraoperative spinal cord injury; and (3) postoperative spinal cord injury (haematoma). Moreover, because an antagonist of ketamine does not exist, we may speculate that an intraoperative wake-up test could have been easier and more rapid with fentanyl–midazolam anaesthesia than with ketamine–midazolam anaesthesia. This may also be important, because fewer neurological deficits occurred if a wake-up test was performed with CSEP monitoring.[2]

There are some limitations of this study. First, some patients scheduled for spine surgery may have abnormal preoperative CSEP. Because we studied patients with normal preoperative CSEP, further studies are thus required to assess the precise effects of ketamine in patients with abnormal preoperative CSEP. Second, the study included only 20 patients, and thus its power may have been too low to detect a significant difference. However, we considered that, if a significant difference does exist, then the magnitude of the difference between the two groups would not be clinically important.

In summary, both ketamine and fentanyl allowed satisfactory CSEP monitoring during major spine surgery, and we found no significant difference in CSEP monitoring between these two anaesthetic regimens. Nevertheless, ketamine was associated with a significant longer delay for first postoperative voluntary motor function assessment and would not allow a rapid peroperative wake-up test. Consequently, there appears to be at present no advantage in the use of ketamine during major spine surgery when CSEP monitoring is required.

# Influence of 0.2 minimum alveolar concentration of enflurane on the ventilatory response to sustained hypoxia in humans

B. NAGYOVA, K. L. DORRINGTON, M. J. POULIN AND P. A. ROBBINS

**Summary**

To determine the influence of 0.2 minimum alveolar concentration (MAC) of enflurane on the time course of ventilation during sustained hypoxia, we studied 10 healthy adult volunteers with and without enflurane. The following design was used: end-tidal $P_{O_2}$ was maintained at 13.3 kPa for 8 min, at 6.7 kPa for 20 min and at 13.3 kPa for 8 min. End-tidal $P_{CO_2}$ was held constant throughout at 0.67 kPa above the subject's natural value. Control experiments were conducted with no hypoxia imposed. During the experiment subjects breathed via a mouthpiece from an automated gas mixing system which controlled end-tidal values. Enflurane reduced baseline (euoxic) ventilation from 20.9 (SEM 2.0) litre min$^{-1}$ to 10.1 (1.0) litre min$^{-1}$ (ANOVA, $P<0.001$). Enflurane reduced the acute ventilatory response to hypoxia (AHVR) from 20.1 (3.3) litre min$^{-1}$ to 5.0 (1.3) litre min$^{-1}$ (ANOVA, $P<0.01$), and the ventilatory off-response at cessation of hypoxia from 11.7 (2.4) litre min$^{-1}$ to 1.8 (0.5) litre min$^{-1}$ (ANOVA, $P<0.02$). There was no significant difference in hypoxic ventilatory decline (HVD) without and with enflurane (8.9 (2.4) litre min$^{-1}$ *vs* 5.5 (1.1) litre min$^{-1}$; ANOVA, ns). These results confirm that 0.2 MAC of enflurane suppressed the acute ventilatory response to hypoxia, but had no significant effect on the subsequent ventilatory decline during sustained hypoxia. (*Br. J. Anaesth.* 1997; **78**: 707–713).

**Key words**

Anaesthetics volatile, enflurane. Ventilation, hypoxic response. Hypoxia.

In humans the time course of ventilation during a period of sustained hypoxia lasting approximately 30 min is characterized by a rapid increase in ventilation over the first few minutes (the acute hypoxic ventilatory response (AHVR)) followed by a gradual decline in ventilation over approximately 20 min (the hypoxic ventilatory decline (HVD), often referred to in the American literature as "roll-off"). HVD cannot be attributed entirely to wash-out of carbon dioxide because the decline is still present even when no changes in arterial carbon dioxide partial pressure (an isocapnic exposure) are permitted to occur during hypoxic exposure.[1] At the relief of isocapnic hypoxia, ventilation usually returns rapidly to its baseline or pre-hypoxic value.

Knill, Manninen and Clement showed the marked depressant effect of sub-anaesthetic concentrations of volatile anaesthetics, including enflurane, on AHVR.[2] Their result has been confirmed by several other groups, including for 0.1 minimum alveolar concentration (MAC) of enflurane,[3] 0.1% inspired halothane,[4] 0.1 MAC and 0.22% (0.15 MAC) halothane.[5 6]

In contrast with the effects of volatile anaesthetics on AHVR, a similar depressant effect on the magnitude of the subsequent ventilatory decline, HVD, has generally not been found. Young, Drummond and Warren[4] and Dahan and colleagues[6] have shown no significant effect of sub-anaesthetic concentrations of halothane on HVD. For isoflurane, Temp, Henson and Ward were unable to show any significant effect of 0.1 MAC of isoflurane on either AHVR or HVD during sustained mildly hypercapnic (end-tidal $P_{CO_2}$ 0.13–0.27 kPa greater than subject's natural value) hypoxia in adults.[7 8] Similar results for HVD were reported by Foo and colleagues[9] for equivalent sub-anaesthetic doses of isoflurane. In our previous study we observed no significant reduction in the magnitude of HVD during 0.1 MAC of enflurane.[3]

The finding that AHVR can be greatly attenuated but HVD relatively unaffected is slightly surprising given that, in conscious humans, (i) the magnitude of HVD correlates with the magnitude of AHVR,[10] (ii) other factors that affect AHVR such as almitrine[11] and somatostatin[12] also alter HVD and (iii) in humans who have undergone peripheral chemodenervation, HVD is abolished together with AHVR.[13] It would appear from such results that both AHVR and HVD are determined by the sensitivity of the peripheral chemoreflex loop and functionally correlated. The usual rapid return of ventilation to its pre-hypoxic value after relief of hypoxia suggests that HVD is a direct measure of the decrease over time in chemoreflex sensitivity.

However, in cats, recent studies have shown considerable differences in the form of the ventilatory response to sustained hypoxia between the awake

---

BEATRIX NAGYOVA, MD, DPHIL, KEITH L. DORRINGTON, DPHIL, DM, FRCA, MARC J. POULIN, MA, PHD, PETER A ROBBINS, BM, BCH, DPHIL, University Laboratory of Physiology, Parks Road, Oxford OX1 3PT. Accepted for publication: February 10, 1997.

and anaesthetized state.[14-18] In awake cats, the form of the ventilatory response to sustained hypoxia is similar to that in awake humans described above. It is clearly asymmetric, with the rapid increase in ventilation at the onset of hypoxia being larger than the rapid decrease at the relief of hypoxia.[10 18 19] On the other hand, in anaesthetized cats, the form of this response is much more symmetric with little difference between the magnitudes of the responses at the onset and relief of hypoxia.[14] This results, at the relief of hypoxia, in a decrease in ventilation to below its pre-hypoxic value, sometimes approaching a period of apnoea.

In most human studies using low doses of anaesthetics the usual finding has been that the response remains asymmetric, with the decrease in ventilation at the relief of hypoxia being smaller than the increase in ventilation at the onset of hypoxia. However, one study by Dahan and colleagues using halothane reported a symmetric response.[6]

The purpose of this study was to determine if low doses of enflurane affect HVD, and to convert the form of the ventilatory response in conscious humans from an asymmetric to a symmetric form, in a manner consistent with the differences between awake and anaesthetized cats. In order to examine this without a likelihood of apnoea or near apnoea occurring after relief of hypoxia and an associated uncontrollable increase in end-tidal $P\text{CO}_2$, the initial ventilations have to be high enough to allow a symmetric off-transient to occur. The strategy of Khamnei and Robbins[19] of conducting the experiments under hypercapnic conditions was used to achieve this.

## Subjects and methods

We studied 10 healthy adult volunteers (aged 26.9 (20–51) yr). All subjects received a written and verbal description of the experiments before they gave their consent. None of the subjects was receiving medication at the time of study and all were asked to refrain from taking food for at least 6 h and drinks for 4 h before the experiments. During the experiments in which no enflurane was administered, subjects were asked to watch television. During experiments in which enflurane was administered subjects were asked to shut their eyes in a partially darkened quiet room. Our aim in reducing the stimulus during enflurane sedation was to achieve as great degree of sedation as possible for the dose of enflurane administered, so as to maximize the difference between the awake and sedated state. A pulse oximeter (Ohmeda Biox 3740) continuously measured arterial oxygen saturation via a finger probe. The study was approved by the Central Oxford Research Ethics Committee.

During the experiment subjects were seated in a comfortable chair and breathed via a mouthpiece from an automated gas mixing system designed to regulate end-tidal values, which provided a steady stream of gas of 66 litre $\text{min}^{-1}$. Respiratory volumes were measured with a turbine volume measuring device.[20] Respiratory flows and timing information were obtained using a pneumotachograph. Respired gas was sampled at the mouth and analysed for $P\text{CO}_2$, $P\text{O}_2$ and enflurane by a mass spectrometer (Airspec 3000, Airspec Ltd., Biggin Hill, Kent, UK). All variables were recorded in real time with a 50-Hz sampling speed by an IBM PC computer. This computer executed a peak-picking program in real time to determine inspiratory and expiratory volumes and durations, and end-tidal $P\text{CO}_2$ ($P\text{E}'_{\text{CO}_2}$) and $P\text{O}_2$ ($P\text{E}'_{\text{O}_2}$). Breath-by-breath end-tidal values were passed to a second computer controlling the gas mixing system. This computer compared actual $P\text{E}'_{\text{CO}_2}$ and $P\text{E}'_{\text{O}_2}$ with the desired values, and adjusted the inspiratory gas mixture to maintain the desired end-tidal values independently of changes in ventilation. Details of the dynamic end-tidal forcing technique and gas mixing system have been described in more detail elsewhere.[21 22]

Enflurane was administered using a vaporizer (Penlon Ltd, Abingdon, UK) through which an air flow of 6–10 litre $\text{min}^{-1}$ was used. The mass spectrometer was calibrated using a standard gas mixture of 0.419% enflurane in air (British Oxygen Company, London; enflurane concentration certified to be within the range 0.398–0.440%). The mass number used for enflurane was 51. During experiments in which enflurane was administered the end-expired enflurane concentration was held constant at 0.34% by manual adjustment of the inspired concentration. During experiments in which no enflurane was administered the vaporizer was kept in the off position.

### EXPERIMENTAL DESIGN

Each subject was studied twice, on separate days. On each day four different tests were studied: (1) 0.2 MAC of enflurane with hypoxia, (2) 0.2 MAC of enflurane with euoxia, (3) no enflurane with hypoxia and (4) no enflurane with euoxia. In tests involving a period of hypoxia (hypoxia tests), $P\text{E}'_{\text{O}_2}$ was forced as follows: 8 min at 13.3 kPa, 20 min at 6.7 kPa and 8 min at 13.3 kPa. In tests involving no period of hypoxia (euoxia tests), $P\text{E}'_{\text{O}_2}$ was held constant at 13.3 kPa for 36 min. In both tests $P\text{E}'_{\text{CO}_2}$ was increased 0.67 kPa above the subject's natural value and maintained constant. The order of the tests was randomized and the tests were separated by 30–45-min intervals.

### DATA ANALYSIS

Data from each test were averaged over 60-s intervals. To characterize the change in the fast components of the ventilatory response to sustained hypoxia we used four particular 1-min periods, which are illustrated in figure 1. The four periods were: ventilation during the last minute before the step into hypoxia ($\dot{V}\text{E}_1$, pre-hypoxic or baseline ventilation), peak ventilation during the first 5 min of the hypoxic period ($\dot{V}\text{E}_2$, peak ventilation), ventilation during the last min of hypoxia ($\dot{V}\text{E}_3$, depressed ventilation) and minimum ventilation during the first 5 min after return to euoxia ($\dot{V}\text{E}_4$, post-hypoxic ventilation). The acute hypoxic ventilatory response (on-response, AHVR) was then taken as the

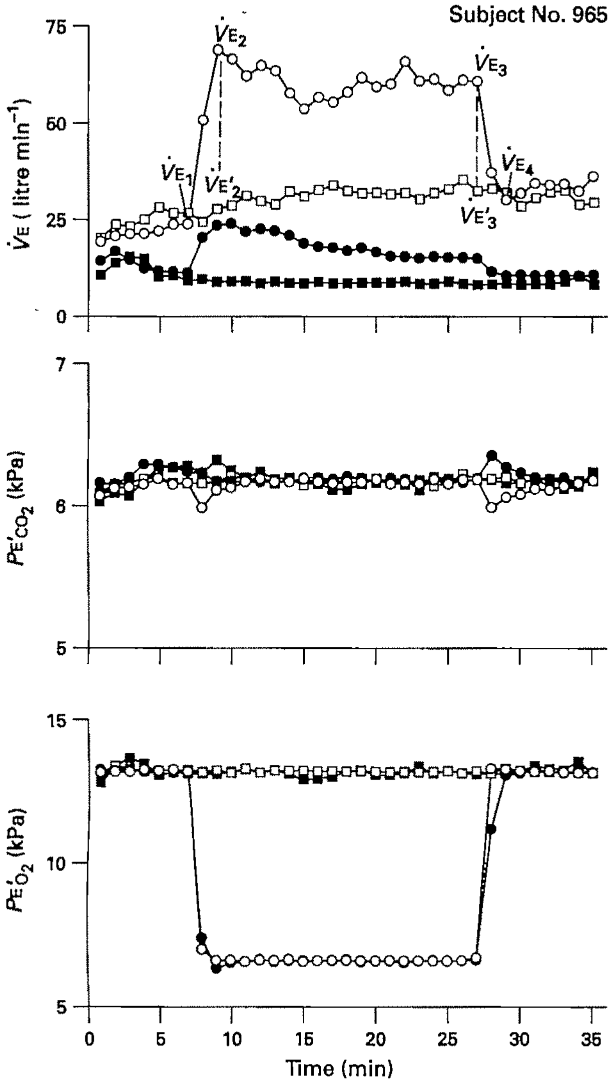

*Figure 1* Subject No. 965. Minute averages. Ventilation ($\dot{V}$E), end-tidal carbon dioxide partial pressure ($P$E$'_{CO_2}$) and end-tidal oxygen partial pressure ($P$E$'_{O_2}$) during hypoxia (circles) and euoxia (squares) tests. Open symbols represent studies without enflurane (○, □) and closed symbols (●, ■) studies with enflurane. Data shown are typical of those for all subjects. $\dot{V}$E$_1$, $\dot{V}$E$_2$, $\dot{V}$E$_3$, $\dot{V}$E$_4$, $\dot{V}$E$'_2$ and $\dot{V}$E$'_3$ indicate ventilations referred to in the text.

difference between peak ventilation and pre-hypoxic ventilation ($\dot{V}$E$_2-\dot{V}$E$_1$). The magnitude of the off-response was calculated as the difference in ventilation between the depressed ventilation and post-hypoxic ventilation ($\dot{V}$E$_3-\dot{V}$E$_4$). The decline in ventilation during hypoxia was corrected for changes in ventilation during the euoxia tests. Thus HVD was calculated using the values of ventilation ($\dot{V}$E$'_2$ and $\dot{V}$E$'_3$) measured during euoxia tests corresponding in time to peak and depressed ventilation (fig. 1). We used the formula: HVD$=(\dot{V}$E$'_2-\dot{V}$E$'_3)-(\dot{V}$E$'_2-\dot{V}$E$'_3)$.

The significance of differences in baseline ventilation, AHVR, HVD and off-response between the two pharmacological conditions was assessed by analysis of variance (ANOVA; balanced design). The analysis was run within MS Windows for Workgroups 3.11 on a Dell XPS P120c PC, using the Minitab for Windows software package. A probability level of less than 0.05 was taken as statistically significant.

## Results

Three of the initial 13 subjects recruited for the study failed to complete the experiments; one because of the excitation, nausea and discomfort during enflurane inhalation and the other two because they found they could not afford the time. The remaining 10 subjects completed the study without any adverse effect. During the enflurane experiments the level of sedation was intense. All of our subjects performed the enflurane experiments with closed eyes. In four subjects we observed airway obstruction with enflurane; this was relieved in all cases by gentle manual extension of the head, traction on the mandible, or both. One subject included in the study had some mild excitation. Mean values for inspired and end-tidal anaesthetic concentrations are shown in table 1. MAC for enflurane was taken to be 1.7%.[23]

End-tidal gas profiles for each test and each pharmacological condition are given in table 2. Figure 2 demonstrates the quality of the end-tidal gas control and ventilatory responses of one subject (No. 960) for the hypoxia and euoxia tests for both pharmacological conditions, each repeated twice. In the hypoxia test the steps of $P$E$'_{O_2}$ into and out of hypoxia were rapid (fig. 2, left bottom panel; for means see fig. 3C). In the euoxia test, $P$E$'_{O_2}$ was maintained constant (fig. 2, right bottom panel; for means see fig. 3C). In both tests $P$E$'_{CO_2}$ remained constant with the exception of a small increase immediately after the step out of hypoxia in the presence of enflurane (fig. 2, middle panels; for means see fig. 3B).

Figure 3 illustrates mean ventilations for all 10 subjects in the euoxia and hypoxia tests under two pharmacological conditions. All subjects showed biphasic ventilatory responses to sustained hypoxia

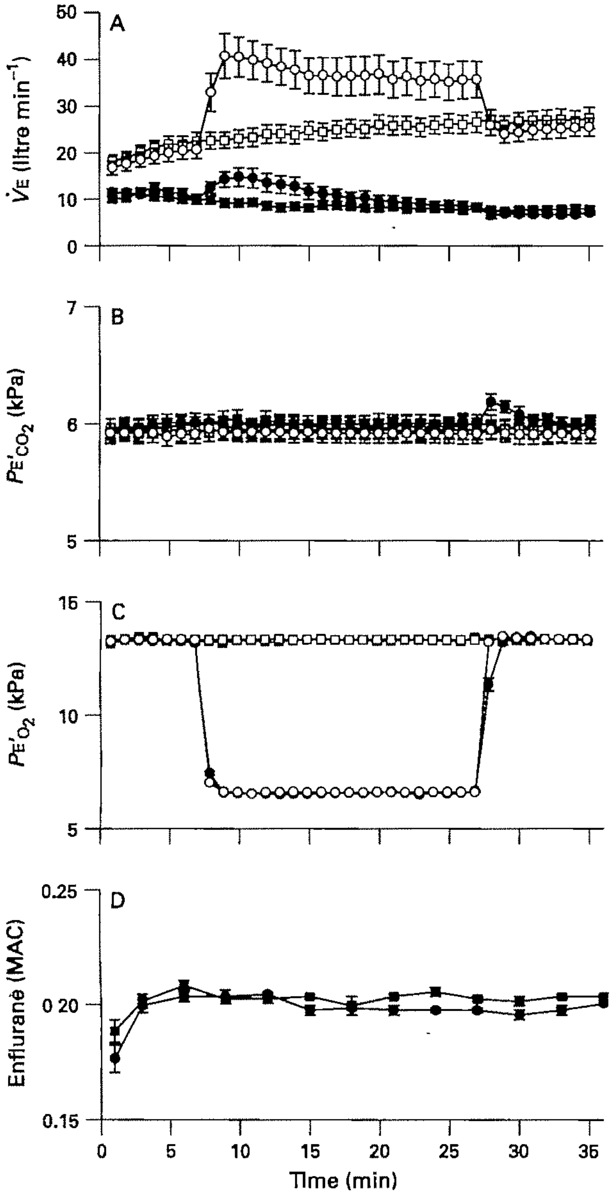

*Figure 3* Mean values for all 12 subjects for ventilation ($\dot{V}$E) (A), end-tidal carbon dioxide partial pressure ($P$E'$_{\text{CO}_2}$) (B) and end-tidal oxygen partial pressure ($P$E'$_{\text{O}_2}$) (C). ○=Hypoxia tests without enflurane; ●=hypoxia tests with enflurane; □=euoxia tests without enflurane; ■=euoxia tests with enflurane. Also shown is the end-tidal enflurane concentration in euoxia (■) and hypoxia (●) (D).

when no enflurane was administered. The biphasic responses to hypoxia were sometimes less obvious during enflurane sedation. The ventilatory responses to hypoxia were generally greater in the absence of enflurane than during enflurane sedation. In the absence of enflurane in the euoxia test ventilation increased gradually over the whole experimental period (fig. 3A), whereas in the presence of enflurane in the euoxia test, ventilation decreased gradually over most of the time (fig. 3A). In the presence of enflurane, the increase in $P$E'$_{\text{CO}_2}$ failed to increase ventilation substantially as was planned (fig. 3A).

Individual values for baseline ventilation, AHVR, HVD and off-responses together with their means are shown in table 3. There was a significant reduction in baseline ventilation ($F$=21.71, $P$<0.001), AHVR ($F$=13.04, $P$<0.01) and off-response ($F$=8.86, $P$<0.02) when comparing enflurane administration with control. In contrast with these findings for baseline ventilation, AHVR and the off-response, there was no significant difference in the magnitude of HVD between the two pharmacological conditions ($F$=1.697, ns).

As an alternative to comparing absolute values for AHVR, HVD and off-response with and without enflurane, it is also possible to compare AHVR, HVD and off-responses with and without enflurane when they are expressed as ratios of baseline ventilation ($\dot{V}$E$_1$) before hypoxia is imposed. Under these conditions AHVR/$\dot{V}$E$_1$ and off-response/$\dot{V}$E$_1$ were both reduced significantly by enflurane ($F$=12.85, $P$<0.01; $F$=12.12, $P$<0.01, respectively), demonstrating that the effect of enflurane was greater on AHVR and off-response than on baseline ventilation. In contrast with the significant findings for AHVR/$\dot{V}$E$_1$ and off-response/$\dot{V}$E$_1$, there was no significant effect for HVD/$\dot{V}$E$_1$ ($F$=0.45, ns). This suggests that our study could not distinguish between the magnitude of HVD remaining constant with and without enflurane and the magnitude of HVD diminishing in proportion to baseline ventilation.

In order to determine if our study could distinguish between HVD remaining constant and HVD changing in proportion to AHVR, we compared the effect of enflurane on HVD/AHVR. A parametric test of significance was inappropriate in this case because of a number of small values of AHVR giving rise to very large values for HVD/AHVR. To overcome this, a non-parametric test (Friedman test) was used, which demonstrated a significant increase in HVD/AHVR with enflurane ($S$=6.40, $P$<0.02).

In order to see if peripheral chemoreflex sensitivity to hypoxia remained unchanged during sustained hypoxia, we compared the magnitude of AHVR and off-response in both pharmacological conditions. The off-response was significantly smaller than AHVR in both cases ($t$ test, $P$<0.001 without enflurane, $P$<0.01 with enflurane). However, the ratio of off-response to AHVR did not differ significantly with and without enflurane ($F$=0.54, ns), suggesting that the proportionate decline in the ventilatory sensitivity to hypoxia was unchanged by enflurane.

## Discussion

The experiments were performed against a background of mild hypercapnia in order to increase the level of ventilation before induction of hypoxia. The idea behind this was that the magnitude of the rapid decrease in ventilation after relief of hypoxia would then not be limited by the need to maintain some basal level of ventilation,[19] that is ventilation would then be able to decrease well below the pre-hypoxic level but still be above the normal eucapnic level. In this respect our study was unsuccessful, as the level of sedation was sufficiently intense effectively to bring ventilation back to basal levels despite the increase in end-tidal $P$CO$_2$. Consequently, conclusions relating to the magnitude of the off-transient during enflurane sedation from this study should be drawn with care (see below).

In addition to performing the hypoxia experiments, we also performed the experiments without hypoxia because we were aware of the possibility that ventilation under the condition of moderate hypercapnia might change gradually with time.[19 24 25] These experiments enabled us to control for any gradual change in hypercapnia over time when interpreting the response to sustained hypoxia. We found that under moderate hypercapnic conditions, euoxic ventilation increased gradually over the whole experimental period in subjects exposed to no enflurane, and decreased gradually in subjects exposed to enflurane. This finding was unexpected, and raises the possibility that the effects of constant end-tidal enflurane were not steady throughout the exposure, but rather that the level of sedation increased progressively.

### ACUTE HYPOXIC VENTILATORY RESPONSE (AHVR): EFFECT OF LOW-DOSE ENFLURANE

The observation that a sub-anaesthetic concentration of enflurane (0.2 MAC) markedly depressed the ventilatory response to acute hypoxia was no surprise.[2 3] Knill, Manninen and Clement reported a 55% reduction in AHVR at 0.1 MAC of enflurane.[2] We found a significant reduction in AHVR of 75%. In our previous study we observed that AHVR was reduced by 20%, 44% and 55% at 0.05, 0.1 and 0.2 MAC of enflurane, respectively.[3] This indicated a steep dose-response curve for the effects of sub-anaesthetic concentrations of enflurane on hypoxic drive. The somewhat greater reduction in AHVR found in this study for 0.2 MAC of enflurane compared with our previous study may be because of different levels of stimulation of our subjects in the two studies. In the previous study[3] subjects were asked to watch television and remain attentive, whereas in this study subjects were asked to close their eyes and the room was partially darkened and kept quiet.

### HYPOXIC VENTILATORY DECLINE (HVD)

We were unable to detect a significant effect of 0.2 MAC of enflurane on hypoxic ventilatory decline. This is consistent with earlier studies on halothane,[4 6] isoflurane[7-9] and enflurane[3] and supports the notion that AHVR and HVD can be targeted separately and may therefore arise via independent mechanisms. Thus in a functional sense, enflurane would appear to affect the ventilatory response to sustained hypoxia in a manner similar to that of dopamine,[26] producing a reduction in AHVR while HVD is unchanged.

We have noted, however, that our study did not have sufficient power to distinguish between the magnitude of HVD remaining constant with and without enflurane and the magnitude of HVD diminishing with enflurane in proportion to baseline ventilation. Our statistical analysis does, however, demonstrate as unlikely that HVD is reduced by enflurane in proportion to AHVR. This in turn suggests that enflurane does not have the effect of modifying the whole ventilatory profile ($\dot{V}_{E_1}$, AHVR, HVD) at all times by the same proportionate reduction.

It is important, however, to bear in mind one possible interpretation of our measurement of a relatively large HVD (5.5 litre min$^{-1}$, table 3) in the presence of enflurane, namely that there may have been a progressive intensification of the effect of enflurane on the peripheral chemoreflex during the hypoxia tests and this would have confounded our attempt to measure HVD in the presence of a constant level of anaesthesia. In effect the "acute" component of the ventilatory response to hypoxia may have been steadily declining through a progressive intensification of the effects of enflurane during the 20-min hypoxic exposure, rendering our measurement of HVD an overestimate. It is to be noted that, although the formula for calculating HVD allows for any progressive effects of enflurane on euoxic ventilation, it cannot allow for a progressive depression by enflurane of the peripheral chemoreflex. An experimental observation that supports this notion is that enflurane reversed the normal progressive increase in ventilation observed with hypercapnia during euoxia. The simplest interpretation of this finding is that the effects of enflurane are not steady, but becoming progressively more intense. However, we know of no evidence that the central neural effects of inhalation anaesthesia change progressively with time in the presence of a constant end-tidal pressure of the anaesthetic over the duration studied here.

### AHVR *VS* OFF-TRANSIENT: EFFECT OF LOW-DOSE ANAESTHETICS

Our observation that in the presence of enflurane the rapid decrease in ventilation at cessation of hypoxia was not similar in magnitude to AHVR seems at variance with the findings of Dahan and coworkers.[6] They studied the effects of 0.15 MAC of halothane on the ventilatory response to sustained mild hypercapnic hypoxia (end-tidal $P\text{CO}_2$ 0.13 kPa above subject's natural value). They observed a small ventilatory undershoot after relief of hypoxia in the absence of anaesthetic, but a larger undershoot in the presence of halothane. Their finding that there was no significant difference in the magnitude of AHVR and the off-response (AHVR=3.6 litre min$^{-1}$; off-response=3.9 litre min$^{-1}$) in the presence of halothane, suggested that the peripheral reflex sensitivity remained unchanged by sustained hypoxia under these conditions.

Our study was designed to provide sufficient elevation of pre-hypoxic ventilation to enable a symmetric off-transient to occur in the presence of enflurane without the limitation of hypopnoea or apnoea on the transition from hypoxia to euoxia. Under enflurane sedation, however, our technique of using moderate hypercapnia failed to achieve a substantial increase in ventilation above normal levels, and the design must therefore be regarded as having failed in this respect. The extent to which a persistent minimum ventilation linked to wakefulness (or "ventilatory dog-leg", as it is often known in the context of studies of hypercapnic sensitivity) is retained in humans under sedation remains uncertain, and with it the extent to which ventilation would need to be increased to permit a symmetrical off-response after a period of sustained hypoxia. It would be informative to repeat administration of enflurane in the presence of a substantially higher level of hypercapnia.

LABORATORY INVESTIGATIONS

# Effect of exogenous nitric oxide and superoxide on interleukin-8 from human polymorphonuclear leucocytes

B. H. CUTHBERTSON, H. F. GALLEY AND N. R. WEBSTER

## Summary

Patients with acute inflammatory lung injury are commonly treated with inhaled nitric oxide. Nitric oxide has profound immunoregulatory effects. Increased concentrations of the cytokine interleukin-8 (IL-8) in bronchoalveolar lavage fluid has been associated with disease severity. We have investigated the effects of a nitric oxide donor and a combined nitric oxide–superoxide donor on lipopolysaccharide-mediated accumulation of IL-8 from cultured human neutrophils. Interleukin-8 was measured in culture supernatant after 20 h using enzyme immunoassay. The combined nitric oxide–superoxide donor, 3-morpholinosydnonimine (SIN-1), dose-dependently decreased lipopolysaccharide-mediated IL-8 accumulation ($P<0.01$). SIN-1 also decreased IL-8 accumulation from unstimulated neutrophils ($P<0.001$). In contrast, the pure nitric oxide donor, 1,2,3,4-oxatriazolium 5-amino chloride (GEA-3162), increased stimulated IL-8 accumulation ($P<0.01$) and also increased IL-8 accumulation in unstimulated cells ($P<0.002$). Nitric oxide and superoxide have profound effects on IL-8. These results have important implications for the treatment of patients with acute lung injury with inhaled nitric oxide. (*Br. J. Anaesth.* 1997; **78**: 714–717).

**Key words**
Polypeptides, cytokines. Pharmacology, nitric oxide. Lung, damage. Lung, adult respiratory distress syndrome.

Nitric oxide has been found to have many biological roles within the body and nitric oxide gas is used as a selective pulmonary vasodilator in critically ill patients with acute respiratory distress syndrome (ARDS).[1] A variety of mediators have been shown to reflect the severity of lung inflammation in ARDS. Concentrations of the cytokine interleukin-8 (IL-8) in bronchoalveolar lavage fluid correlated with the development of ARDS[2] and increased IL-8 concentrations early in the disease process correlated with mortality.[3] In addition, inhaled nitric oxide therapy modulates increased cytokine concentrations, including IL-8, in patients with ARDS.[4]

Nitric oxide and its metabolite peroxynitrite are known to have a profound effect on the inflammatory process as it is now known that activated white cells release nitric oxide in addition to superoxide anion during the respiratory burst.[5] There is however, little information on the possible interaction of nitric oxide and the metabolites of nitric oxide on the regulation of the inflammatory process. Such regulation is governed by circulating inflammatory mediators which are released from immune cells and affect the functioning of other cells. Information on this interaction is important because of the increasing use of exogenous nitric oxide in the treatment of refractory hypoxia and pulmonary hypertension in ARDS.

We have therefore investigated the effects of nitric oxide and superoxide on cytokine production by polymorphonuclear leucocytes both with and without lipopolysaccharide and in the presence of either the nitric oxide donor 1,2,3,4-oxatriazolium 5-amino chloride (GEA-3162) or the combined nitric oxide and superoxide donor 3-morpholinosydnonimine (SIN-1).

## Materials and methods

Polymorphonuclear leucocytes were isolated from a single volunteer for all experiments using a single step density gradient procedure. Arterial blood was added to sterile preservative-free heparin (10 u./ml of blood) and layered onto Polymorphprep separation medium (Nycomed UK Ltd, Birmingham, West Midlands, UK). After centrifugation at 475 *g* for 35 min at 20 °C, the mononuclear cell band was discarded and polymorphonuclear leucocytes (PMN) were retrieved and washed in Dulbecco's modification of Eagle's basal medium (DMEM, ICN Biomedicals Ltd, Thame, Oxon, UK). Contaminating erythrocytes were removed by hypotonic shock and cells were washed three times in DMEM before being resuspended, counted and adjusted to $3\times10^6$ cells/ml.

Replicate samples ($1.5\times10^6$ cells) were placed into 24-well tissue culture plates and lipopolysaccharide to a final concentration of 1.7 $\mu$g ml$^{-1}$ (LPS, from *E. coli* strain 0111.B4, Sigma-Aldrich Chemical Co. Ltd, Poole, Dorset, UK) or phosphate-buffered

saline blank was added as appropriate. To each well was also added varying concentrations of the nitric oxide donors. The agents used were 3-morpholinosydnonimine hydrochloride (SIN-1) (Alexis Corporation, Nottingham, UK) which is a metabolite of the vasodilator molsidomine and is a nitric oxide and superoxide anion donor and thus considered a peroxynitrite releasing compound. In addition, to some cells was added 1,2,3,4-oxatriazolium-5-amino-3-(3,4-dichlorophenyl)-chloride (GEA-3162) (Alexis Corporation, Nottingham, UK) which is a water soluble nitric oxide donor. The concentrations used were 10, 100 and 1000 μmol litre$^{-1}$ for SIN-1 and 0.01, 0.1 and 1.0 μmol litre$^{-1}$ for GEA-3162 in phosphate-buffered saline. Non-LPS stimulated neutrophils were also incubated with SIN-1 100 μmol litre$^{-1}$ or GEA-3162 1 μmol litre$^{-1}$ as controls.

Tissue culture plates were incubated at 37 °C in an atmosphere of 5% carbon dioxide–95% air for 20 h. Culture medium was removed for measurement of IL-8 using solid phase sandwich enzyme-linked immunosorbent assay (ELISA, R&D Systems Europe Ltd, Abingdon, Oxon, UK). Results are expressed as pg/10$^6$ cells. The assay is highly specific for IL-8 and shows no cross-reactivity for any of the other human cytokines tested. Within-assay precision was 3.2% ($n$=20) and between-assay precision 9.5% ($n$=20). Cells were detached for viability count using the vital stain trypan blue.

### STATISTICAL ANALYSIS

Data are presented as median (range) and represent 5–6 separate experiments. Statistical analysis was performed using Microsoft Excel with Astute add-in and data were analysed using Kruskal–Wallis analysis of variance or Mann–Whitney $U$ test as appropriate, with $P<0.05$ being considered statistically significant.

## Results

Unstimulated polymorphonuclear leucocytes produced detectable basal concentrations of IL-8 which were increased when cells were incubated with LPS ($P<0.0001$; figs 1, 2). Incubation with SIN-1 caused concentration-dependent depression of IL-8 accumulation in culture medium of LPS-stimulated cells ($P<0.01$; fig. 1). Addition of SIN-1 1000 μmol litre$^{-1}$ to cells in the absence of stimulation with LPS also caused a reduction in basal IL-8 accumulation ($P<0.001$; fig. 1).

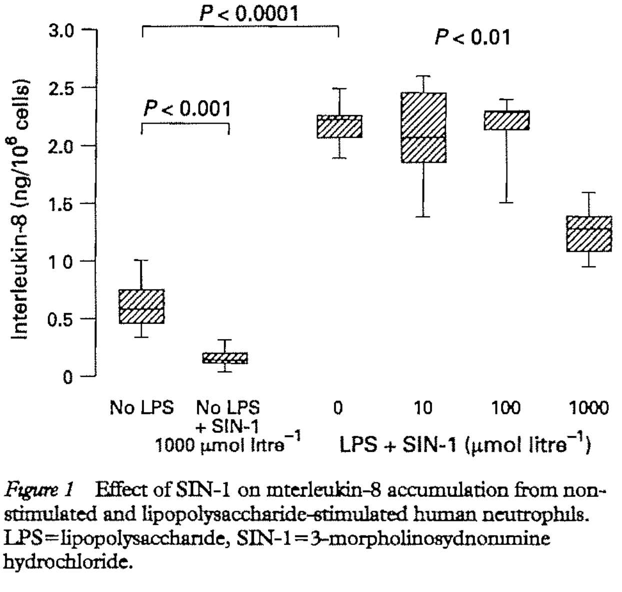

*Figure 1* Effect of SIN-1 on interleukin-8 accumulation from non-stimulated and lipopolysaccharide-stimulated human neutrophils. LPS=lipopolysaccharide, SIN-1=3-morpholinosydnonimine hydrochloride.

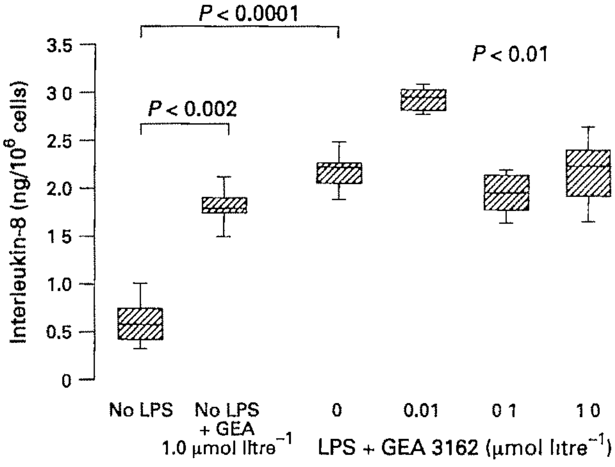

*Figure 2* Effect of GEA-3162 on interleukin-8 accumulation from non-stimulated and lipopolysaccharide-stimulated human neutrophils. LPS=lipopolysaccharide, GEA-3162=1,2,3,4-oxatriazolium-5-amino-3-(3,4-dichlorophenyl)-chloride.

In contrast, GEA significantly increased IL-8 accumulation from both LPS-stimulated and unstimulated cells ($P<0.01$ and $P<0.002$ respectively; fig. 2).

Trypan blue staining showed that cell viability in SIN-1 and GEA-3162 treated cells after 20 h incubation was similar to that of cells in the absence of these agents.

## Discussion

We have shown that exogenous nitric oxide and a combination of nitric oxide–superoxide has a marked effect on the accumulation of IL-8 from LPS-stimulated human polymorphonuclear leucocytes. IL-8 is a potent neutrophil chemotactic and activating factor released by neutrophils in a self-amplifying process in response to inflammatory stimuli. IL-8 has been implicated in the pathogenesis of ARDS both as a marker of onset and severity of ARDS,[2] and concentrations in bronchoalveolar lavage fluid correlate with mortality.[3] It is a potent chemoattractant and has an important role in the recruitment and activation of neutrophils into the lung. Activated neutrophils via the release of cytokines, proteinases, hypochlorous acid, oxygen-derived free radicals and nitric oxide are important in the pathophysiology of ARDS as these inflammatory mediators may result in tissue damage. Further release of these chemotactic factors potentiates this inflammatory process. Factors which regulate the production and release of IL-8 may, therefore, have a major role in altering the regulation of inflammation. The release of IL-8 by the same cell type as that on which it acts has important implications as it so acts to amplify the inflammatory process occurring at that particular site. For these reasons the study of isolated neutrophils *in vitro* provides a model of the pathophysiological processes in ARDS. The dedicated nitric oxide donor GEA and the combined nitric oxide–superoxide anion donor SIN-1 had markedly different effects on IL-8. Such changes have clear implications for patients receiving inhaled nitric oxide for the acute inflammatory process of ARDS.

Exogenous nitric oxide has been shown to have various effects on the activity of neutrophils. Production of the arachidonic acid product leukotriene $B_4$ is dose-dependently reduced in the presence of either SIN-1 or GEA-3162 in calcium ionophore-stimulated neutrophils.[6] In addition, there is a dose-dependent reduction in leukotriene $B_4$ formation in formyl-methionyl-leucyl-phenylalanine- (FMLP) stimulated neutrophils in the presence of SIN-1.[7] There is some evidence of a biphasic effect of SIN-1 on the oxidative burst activity (superoxide production) of opsonised zymosan-activated neutrophils.[8] Other investigators have shown dose-dependent reduction in superoxide production by SIN-1 in stimulated and non-stimulated neutrophils.[9] Nitric oxide can inhibit the enzyme NADPH oxidase which produces superoxide.[10] Nitric oxide has also been shown to reduce neutrophil adherence and migration and thus accumulation.[11]

We have found a different effect of dedicated nitric oxide donor compared with the combined nitric oxide–superoxide anion donors on human polymorphonuclear leucocytes. Exogenous nitric oxide alone increased the accumulation of IL-8 in both LPS-stimulated and unstimulated neutrophils. The combined nitric oxide–superoxide anion donor (effectively a peroxynitrite donor) caused a concentration-dependent reduction in IL-8 production. This is in contrast with a previous study of human melanoma cells in which both SIN-1 and the dedicated nitric oxide donors S-nitroso-L-glutathione and S-nitroso-N-acetylpenacillamine caused an increase in IL-8 at the transcriptional level.[12] Another study using a human endothelial cell line showed that exogenous nitric oxide increased IL-8 release.[13] These effects may represent different actions on the transcription factor nuclear factor κB (NFκB) in the cell types described. This transcription factor is activated by external cell signals and allows rapid production of immunologically active compounds such as cytokines and nitric oxide synthase. It is known that activation of NFκB is stimulated by hydrogen peroxide and possibly other free radicals[14] and that nitric oxide also activates NFκB in some cell types,[12 15] although in human endothelial cells NFκB is inhibited by nitric oxide.[16] The effect of nitric oxide and superoxide on NFκB activation or inhibition in human neutrophils is not known. It is also possible that nitric oxide and superoxide could affect transcriptional, translational, post-translational and stability or excretion of IL-8 after its production. Further research to elucidate the role of free radicals on inflammatory responses is required

The relative levels of nitric oxide and peroxynitrite could determine the recruitment of neutrophils into the lung either through a direct effect of nitric oxide on neutrophil adherence or through IL-8 induced chemotaxis. During inhaled nitric oxide therapy in ARDS this balance may be disturbed thereby resulting in alteration of the inflammatory process. Inhaled nitric oxide therapy has been shown to decrease the high IL-6 and IL-8 concentrations in bronchoalveolar lavage fluid in patients with ARDS.[4] These results contradict our findings but could be explained by the high availability of superoxide in inflammatory lung diseases leading to peroxynitrite production.[17] This would agree with work that showed the presence of nitrotyrosin residues (a marker of peroxynitrite damage) within the lung of all patients with ARDS and would explain decreased IL-8 concentrations in bronchoalveolar lavage fluid in these patients.[4 18]

The precise role of exogenously administered nitric oxide in the regulation of the inflammatory process still needs to be established in the intact human.

# Effects of volatile anaesthetics on human neutrophil oxidative response to the bacterial peptide FMLP

D. FRÖHLICH, G. ROTHE, B. SCHWALL, P. SCHMID, G. SCHMITZ, K. TAEGER AND J. HOBBHAHN

## Summary

The oxidative burst response of neutrophils to bacteria is crucial for effective host defence. It has been shown that inhalation anaesthetics interfere with neutrophil function and the object of this study was to characterize the mechanisms of interaction of volatile anaesthetics with the oxidative response of neutrophils. $H_2O_2$ production by neutrophils after stimulation with the bacterial peptide, *N*-formyl-L-methionyl-L-leucyl-phenylalanine (FMLP) and phorbol-12-myristate-13-acetate (PMA) was measured by oxidation of the indicator dye dihydrorhodamine using flow cytometry. FMLP binds to a specific surface receptor on neutrophils and initiates via receptor specific signal transduction respiratory burst as an all-or-none event, whereas PMA is an artificial activator of protein kinase C, which bypasses receptor-mediated signal transduction. In the presence of halothane, enflurane and sevoflurane, there was an increase in activation threshold on FMLP stimulation. Overall, this correlated with reduced $H_2O_2$ production. Isoflurane had no effect. In the presence of desflurane, however, $H_2O_2$ production of neutrophils increased two-fold, followed by transient suppression of neutrophil function. PMA-induced $H_2O_2$ generation was unchanged in the presence of volatile anaesthetics. We conclude that volatile anaesthetics modulated FMLP receptor-dependent signal transduction upstream of protein kinase C activation, leading to a reduced response in the presence of halothane, enflurane and sevoflurane and to an increased response in the presence of desflurane. (*Br. J. Anaesth.* 1997; **78**: 718–723).

**Key words**
Immune response. Blood, leucocytes Blood, neutrophils. Anaesthetics volatile, desflurane. Anaesthetics volatile, enflurane. Anaesthetics volatile, halothane. Anaesthetics volatile, isoflurane Anaesthetics volatile, sevoflurane.

Neutrophil granulocytes are a major component of the non-antigen-specific, cell-mediated immune system. Activated by chemotactic signals, neutrophils migrate towards infected tissue ingesting and killing bacteria. A crucial mechanism of bacterial killing by neutrophils is generation of reactive oxygen derivatives. Because of the high oxygen uptake during generation of reactive oxygen species, this reaction has also been called respiratory burst.[1]

The defence mechanism of oxygen radical production may be impaired, for example after drug exposure or during disease. Numerous studies have shown suppression of neutrophil oxidative function with halothane[2–6] and enflurane.[5–7] Isoflurane appears to have no, or only a minimal effect on neutrophils.[3–5 7]

We have investigated the effects of several halogenated, volatile anaesthetics on the production of reactive oxygen derivatives in human neutrophils. Two different stimuli, *N*-formyl-methionyl-leucyl-phenylalanine and phorbol-13-myristate-12-acetate, were used to trigger respiratory burst in order to discriminate between receptor-dependent and independent mechanisms, respectively.

The flow cytometric assay used in this study allows quantification of the heterogenous oxidative response of neutrophils at the single cell level with low degrees of stimulation.

## Materials and methods

The volatile anaesthetics used were obtained from the following companies: halothane from Hoechst, Germany; enflurane, sevoflurane and isoflurane from Abbott, Germany; desflurane from Pharmacia, Sweden. Carboxy-seminaphthorhodafluor-1-acetoxymethylester (SNARF1/AM) and dihydrorhodamine-123 (DHR) were obtained from Molecular Probes, Eugene, OR, USA. Dulbecco's phosphate-buffered saline (PBS) with $Ca^{2+}$ and $Mg^{2+}$ was obtained from Gibco-Life Technologies, Germany. *N*-formyl-L-methionyl-L-leucyl-phenylalanine (FMLP) and phorbol-12-myristate-13-acetate (PMA) were obtained from Sigma Chemicals,

Deisenhofen, Germany. Propidium iodide (PI) was purchased from Serva, Heidelberg, Germany. DHR, SNARF1/AM and FMLP were kept as stock solutions in dimethylformamide (DMF) and diluted in PBS yielding working concentrations of 100 $\mu$mol litre$^{-1}$ for DHR, and 10 $\mu$mol litre$^{-1}$ for SNARF1/AM, FMLP and PMA. Stock solutions were stored at −70 °C. Standard dye-beads (Quantum 26) for calibration of the flow cytometer were obtained from Flow Cytometry Standards Europe based in Leiden, The Netherlands.

### ISOLATION OF LEUCOCYTES

This study was approved by the local Ethics Committee, and after receiving written informed consent, venous blood was obtained from healthy donors with no history of infection for the 2 weeks before the experiments. The donors ($n$=9) had a mean age of 32 (range 25–39) yr. They had a mean white blood cell count of 6200 (SD 1300)/$\mu$l and haemoglobin concentration was 15.2 (1.8) g dl$^{-1}$. Mean differential leucocyte count was: neutrophils 53 (8) %, lymphocytes 32 (7) %, monocytes 8 (3) %, eosinophils 3 (2) % and basophils 1 (1) %. Blood counts were performed before each experiment with a Technicon H*3 counter (Bayer Diagnostics, Tarrytown, NY, USA). No specimens had to be excluded because of abnormal blood cell counts.

Blood was collected in lithium heparin coated disposable blood sampling tubes (Sarstedt, Nürmbrecht, Germany). Leucocyte isolation was carried out by sedimenting erythrocytes on Ficoll. Heparinized (10 u. ml$^{-1}$) whole blood (3 ml) was layered on top of 3 ml of lymphocyte separation medium (density 1.077 g ml$^{-1}$) from Sigma Chemicals, Deisenhofen, Germany. Erythrocytes aggregated at the interface and settled at room temperature without centrifugation. After 40 min the upper 800 $\mu$l of supernatant leucocyte-rich plasma were withdrawn, avoiding contact with the plasma fraction close to the interface with the separation medium. To avoid artificial activation of cells, the isolation process did not involve lysis, centrifugation or washing procedures.

### RESPIRATORY BURST ASSAY

Each volatile anaesthetic was tested separately *in vitro* with neutrophils from the nine donors at four different concentrations (0, 0.5, 1.0, 2.0 MAC). The MAC values used for this study were: 0.8% for halothane, 1.7% for enflurane, 2% for sevoflurane, 1.2% for isoflurane and 6% for desflurane.[8 9] All anaesthetics were administered as volatile anaesthetic/air mixtures. The respiratory burst assay was performed in a 75 L airtight glovebox. Fresh gas was prepared using a gas mixing unit with calibrated vaporizers (Draeger, Lübeck, Germany). Fresh gas flow, after equilibration of the atmosphere inside the box with high flow rates, was 5 litre min$^{-1}$ during the experiments. Inside the glovebox, samples were kept at 37 °C with a heated aluminium block. To maintain the amount of evaporated water from the samples low, tubes were sealed with gas-permeable parafilm during all incubations. Volatile delivery under the hood was monitored continuously at the site of the sample tubes by a multi-gas analyser (Capnomac Ultima, Datex, Sweden).

Before filling the polypropylene tubes (diameter 10 mm) and adding leucocytes, Dulbecco's PBS was equilibrated with the anaesthetic inside the glovebox by bubbling fresh gas through for 30 min at 37 °C. The leucocyte-rich plasma was suspended 1:50 (20 $\mu$l of leucocytes and 980 $\mu$l of PBS) in pre-equilibrated Dulbecco's PBS and incubated for 20 min at 37 °C. The leucocytes were loaded with the fluorogenic substrates DHR and SNARF1/AM for 10 min. Cells were pre-exposed to the volatile anaesthetics for 30 min. The final concentrations were 1 $\mu$mol litre$^{-1}$ for DHR and 0.2 $\mu$mol litre$^{-1}$ for SNARF1/AM. Thereafter, FMLP or PMA (10 $\mu$l) at a final concentration of 100 nmol litre$^{-1}$ were added to initiate $H_2O_2$ generation. After 15 min of incubation at 37 °C the reaction was stopped on ice. Dead cells were counterstained with PI (10 $\mu$l) at a final concentration of 30 $\mu$mol litre$^{-1}$. Samples were stored on ice in the dark and measured within 1 h. For evaluation of recovery of neutrophil function, the assay was repeated sequentially for both unexposed control and exposed samples: during exposure and 0.5 h, 1 h and 2 h after the end of exposure.

For analysis we used a FACScan flow cytometer (Becton Dickinson, San José, CA, USA) with argon-ion laser excitation at 488 nm, measuring $10^4$ cells of each stained sample. Data were acquired and processed using LYSIS-II software provided by the cytometer manufacturer. In order to obtain absolute calibration of the fluorescence measurements the arbitrary fluorescence units of the cytometer were transformed into molecule equivalent of soluble fluorochrome (MESF) units. Therefore, after each experiment five populations of standard beads (Quantum 26) with a known content of fluorochrome were measured and a linear regression line was calculated. The MESF units were used for absolute quantification of cellular fluorescence, allowing inter-assay and inter-laboratory comparison of data. Dead cells were assessed by their PI fluorescence (above 600 nm). Leucocyte esterase activity, characteristic for viable cells, was determined based on SNARF1-related orange fluorescence. SNARF1/AM is cleaved in vital leucocytes by esterases to fluorescent SNARF1. Neutrophils were identified by their typical side scatter light (SSC) and forward scatter light (FSC) patterns. SSC depends on the granularity of cells, whereas FSC is related to the size of cells.

### GAS CHROMATOGRAPHY/MASS SPECTROMETRY

For assessment of the concentrations of volatile anaesthetics in the fluid phase of our experiments, we used gas chromatography/high resolution mass spectrometry (GC/HRMS) with a HRGC Mega 2 series (Fisons Instruments SpA, Rodano, Italy). Elution was performed on a 20 m×0.27 mm glass capillary column coated with a 2.1-$\mu$m film of PS 090 (Petrarch Systems Inc., Bristol, PA 19007, USA). The carrier gas was hydrogen at a head pressure of 30 kPa (linear flow rate 0.3 m $s^{-1}$). Samples of 0.75 µl were injected into the split injector (temperature 250 °C, split ratio 1:20); oven temperature was kept at an ambient temperature of 24 °C. The mass spectrometer MAT 95 (Finnigan MAT, Bremen, Germany) was run in electron impact mode at 70 eV electron energy (ion source temperature 180 °C). The mass resolution $m/\Delta m$ was set to 7500; the multiplier voltage was 1.4 kV. Typical ions were recorded by single ion monitoring (SIM) using perfluorotributylamine and carbon dioxide, respectively, as references; cycle time was 0.2 s. Quantification was based on signal areas in the mass chromatograms.

### STATISTICAL ANALYSIS

All data are presented as mean (SD) and range. Analysis of variance and the Student–Newman–Keuls test for multiple pairwise comparison at a significance level of $P<0.05$ were used to compare controls and drug-exposed samples. MAC was designated as the independent variable for analysis of variance to evaluate the effects of different concentrations of volatile anaesthetics. To test the significance of differences in the recovery kinetic data, the Student's *t* test was used. We compared mean fluorescence of unexposed controls processed in parallel with volatile anaesthetic-exposed aliquots.

## Results

Figure 1A shows flow cytometric analysis of resting, non-stimulated leucocytes, whereas figure 1B displays the heterogenous reaction of neutrophils on FMLP stimulation. In contrast, the PMA-induced reaction of all cells was homogenous (fig. 1C). The percentage of reacting and non-reacting neutrophils is given on the left of each dot plot. The percentage of dead cells was lower than 0.1% independent of drug exposure or stimulation.

In the presence of halothane the reactive oxygen derivative generation of neutrophils and monocytes was significantly reduced. At 1 MAC mean fluorescence was 50% compared with control (fig. 1D). In the presence of enflurane (2 MAC), $H_2O_2$ generation reached only 60% of control (table 1). The decreased $H_2O_2$ production correlated with a decreased number of reacting neutrophils. Percentages of neutrophils reacting on FMLP stimulation are given in table 2. The effects observed in the presence of halothane and enflurane were also visible with sevoflurane, although the decrease in $H_2O_2$ production was not significant. Isoflurane did not interfere with neutrophil reaction on FMLP stimulation.

In contrast with all other anaesthetics, the oxidative response after stimulation was enhanced in the presence of desflurane. Both mean fluorescence and percentage of neutrophils responding with a

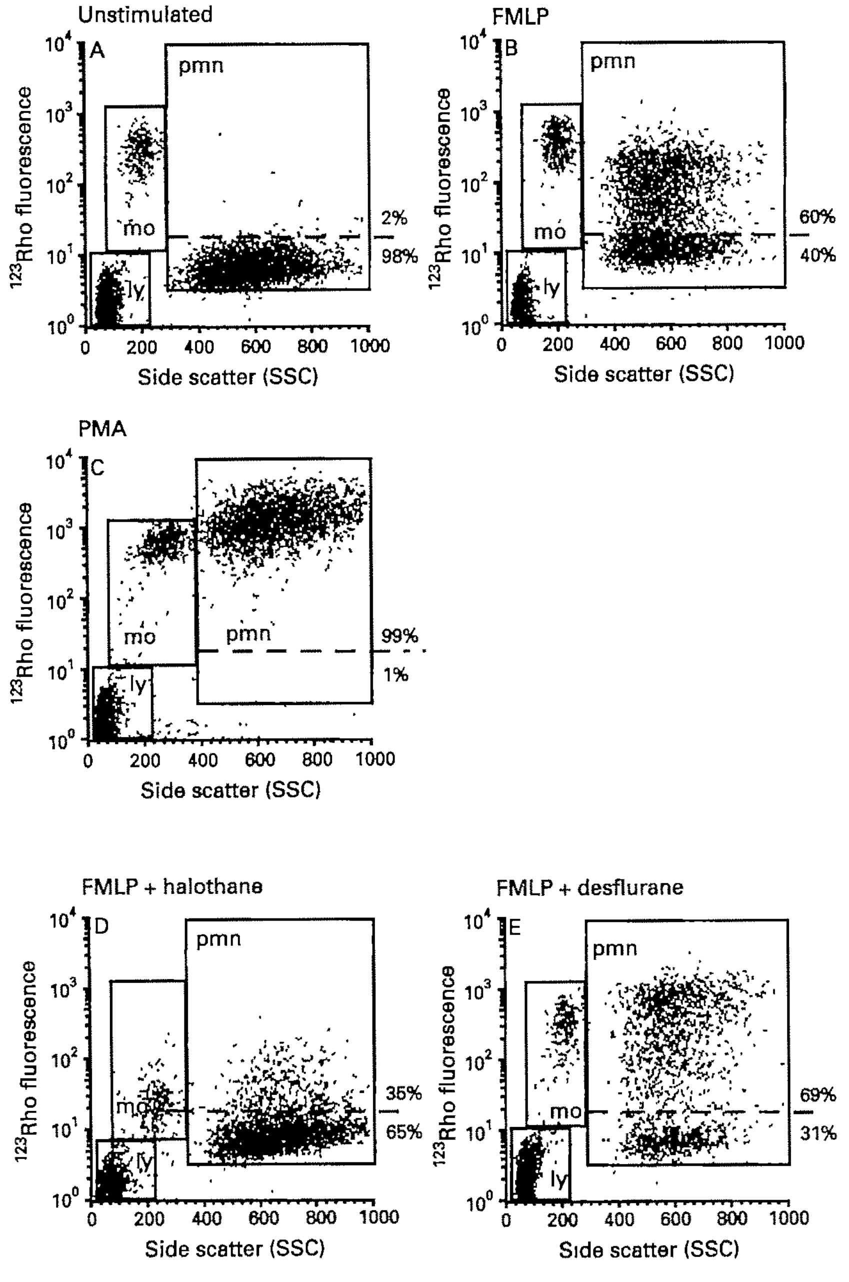

*Figure 1* Flow cytometric analysis of intracellular $H_2O_2$ of 10 000 leucocytes from a representative experiment. The *X*-axis indicates the side scatter (SSC) of leucocytes as a marker of cellular granularity, while the *Y*-axis represents $H_2O_2$ production (rhodamine-123 ($^{123}$Rho) fluorescence) in arbitrary units (neutrophils (pmn), monocytes (mo), lymphocytes (ly)). A: Unstimulated cells; B: cells stimulated with FMLP 100 nmol litre$^{-1}$; C: cells stimulated with PMA 100 nmol litre$^{-1}$; D and E: cells stimulated with FMLP 100 nmol litre$^{-1}$ in the presence of halothane (1 MAC) and desflurane (2 MAC). B serves as a control for D and E. The ratio between reacting and non-reacting cells is given to the right of each dot plot.

respiratory burst reaction were increased compared with controls (fig. 1E, tables 1, 2).

Recovery data are given as the ratio between fluorescence of the exposed and non-exposed samples (table 3). Significant differences between control and drug exposed samples were found for halothane up to 30 min after exposure. Desflurane exposed neutrophils showed transient depression of respiratory burst activity on FMLP stimulation. The impairment lasted less than 2 h.

By GC/HRMS the following buffer/gas partition coefficients and concentrations of volatile anaesthetics for 37 °C and 1 MAC were confirmed: halothane 0.663 and 0.24 (0.01) mmol litre$^{-1}$, enflurane 0.548 and 0.42 (0.02) mmol litre$^{-1}$, isoflurane 0.438 and 0.24 (0.01) mmol litre$^{-1}$, sevoflurane 0.370 and 0.33 (0.01) mmol litre$^{-1}$ and desflurane 0.234 and 0.63 (0.03) mmol litre$^{-1}$. Equilibration was complete after 10 min for all anaesthetics. Ten minutes after removal of the anaesthetic, concentrations in the fluid phase decreased to less than 2% of the initial concentration. The relationship between fluid- and gas-phase concentration was linear in the range relevant to this study.

## Discussion

In this in *vitro* study we have investigated the ability of human neutrophils to form reactive oxygen products after FMLP stimulation during and after exposure to volatile anaesthetics.

Unlike other investigators we used MAC-related concentrations in order to compare equipotent concentrations of anaesthetics. The measured buffer/gas partition coefficients were lower than those coefficients given for blood by other authors and met the coefficients published for saline.[10–12] This may lead to underestimation of the effects presented in this report. In terms of molarity, the MAC-derived differences in concentration were smaller in the fluid phase than in the gas phase of the experiment. For example, 1 MAC of halothane (0.8 vol%) corresponded to 0.24 mmol $litre^{-1}$, whereas 1 MAC of desflurane (6.0 vol%) was only 0.63 mmol $litre^{-1}$.

The small amounts of intracellular $H_2O_2$ generated after stimulation were assessed by quantifying the intracellular oxidation of the indicator dye dihydrorhodamine-123 to rhodamine-123.[13] The former is a non-fluorescent and membrane-permeable fluorogenic substrate whereas the latter oxidation product emits green light (510–530 nm) on excitation.[14] This method has several advantages over those used previously for quantifying neutrophil oxidative function. First, purification of neutrophils, which often leads to artefactual activation of cells, is unnecessary. Second, flow cytometric results are not affected by variations in concentration of neutrophils in the assay, as each individual neutrophil is measured and not the average response of all those assayed. Thus we can show the heterogenous response of neutrophils in an all-or-none reaction after stimulation; only a subset of all neutrophils respond with the respiratory burst reaction on FMLP stimulation while the others remain resting (fig. 1B).

In our study, halothane and enflurane caused a reversible decrease in the formation of $H_2O_2$, which is in accordance with the results of other investigators.[2–7] This inhibition was characterized by a decrease in production of respiratory burst products per neutrophil, and reduction in the number of neutrophils recruited for respiratory burst. Desflurane enhanced the neutrophil response significantly, and a transient decrease in neutrophil oxidative burst activity ensued after removal of anaesthetic. The increased activity not only correlated with increased recruitment of neutrophils, but also enhanced intracellular $H_2O_2$ per cell. Enhanced neutrophil function in the presence of isoflurane has also been shown by Erskine and James[4] and by Nakagawara and colleagues[5] for a concentration corresponding to 2 MAC. The reported effects of isoflurane were not significant in our experiments. Using the receptor independent stimulus PMA, none of the anaesthetics at any concentration had an effect on the oxidative response. The finding of unchanged PMA-induced respiratory burst in the presence of all volatile anaesthetics excludes two potential causes of altered $H_2O_2$ production: scavenging of reactive oxygen derivatives by volatile anaesthetics and direct interference with $H_2O_2$ generating enzymes. Furthermore, Nakagawara and colleagues[5] tested the ability of halothane to scavenge respiratory burst products in cell-dependent and cell-free systems. Neither halothane nor enflurane were able to reduce the amount of generated reactive oxygen products. Thus the significant decrease in $H_2O_2$ production of monocytes in the presence of halothane (fig. 1D) was most likely caused by interference with regulation of the spontaneous oxidative burst of monocytes. This regulation involves signalling pathways different from those mediating neutrophil respiratory burst.

Halothane, enflurane and sevoflurane increased and desflurane decreased the threshold for FMLP-dependent activation such that the number of neutrophils displaying respiratory burst on stimulation declined or increased. PMA activates respiratory burst through the same signal transduction chain as FMLP but at a later activation step. Nakagawara and colleagues[5] investigated the affinity of the FMLP receptor for its agonist in the presence of volatile anaesthetics by measuring the uptake of radioactive labelled FMLP. They found an unchanged affinity of the receptor in the presence of halothane and enflurane. Thus halothane, enflurane and sevoflurane appear to interfere with intracellular signal transduction downstream of the FMLP receptor and upstream of the activation site of PMA.

The bacterial peptide FMLP is a physiological agonist for specific receptors on neutrophils. FMLP has been shown to be a major chemotaxin for neutrophils, and phagocytosis of *Escherichia coli* is mediated mainly by FMLP and its receptor on the neutrophil surface.[15] The concentration of 100 nmol $litre^{-1}$ for FMLP was chosen to allow analysis of the heterogenous response of neutrophils. This concentration also allows comparison with results of other authors.[5] FMLP triggers multiple responses, including chemotaxis, exocytosis of certain enzymes and superoxide generation by the NADPH oxidase complex, the so-called respiratory burst.[1 16–18] Binding of FMLP to the G-protein-coupled receptor induces a temporary increase in phosphatidylinositol-1,4,5-triphosphate, cytosolic calcium, 1,2 diacylglycerol (DAG) and other activators of protein kinase C (PKC).[19 20] Human neutrophils express four PKC isoenzymes ($\alpha$, $\beta$I, $\beta$II, $\zeta$). PKC$\beta$ and $\zeta$ are the most abundant isoforms, while PKC$\alpha$ is hardly detectable. After stimulation with FMLP the PKC isoforms $\beta$I, $\beta$II and $\zeta$ are redistributed from the cytosol to the plasma membrane. PMA is a synthetic analogue of DAG and therefore induces a similar redistribution and activation of PKC, but unlike FMLP the redistribution of PKC is irreversible.[21] The membrane bound form of PKC activates, by intermediate steps, NADPH oxidase. By a single electron transfer, this oxidase transforms molecular oxygen into superoxide anion. Superoxide then dismutates to hydrogen peroxide ($H_2O_2$) inside the phagosomes or in the extracellular space.[1 17] Activation of respiratory burst depends on calmodulin,[22 23] as deduced from experiments using specific antagonists. Calmodulin, an ubiquitous low-molecular-weight protein, regulates the calcium-dependent activity of various enzymes. Périanin, Pedruzzi and Hakim[22] demonstrated that the calmodulin antagonist W-7 dose-dependently enhances and depresses the respiratory burst reaction. Levin and Blanck[24] showed that halothane and isoflurane interfered with the affinity of calmodulin for calcium. Low concentrations of halothane (0.57%) decreased the affinity, whereas higher concentrations (5.7%) significantly increased the ability to bind calcium. The latter effect was found to be irreversible.[24] Isoflurane behaved in a similar way, but halothane was more potent when compared on the basis of MAC values.

These findings may explain the ability of desflurane to enhance and of halothane, enflurane and sevoflurane to lower respiratory burst by interfering with calmodulin, in a manner similar to the known calmodulin antagonist W-7.[22] Thus desflurane might interfere in the same manner as high-dose isoflurane in the experiments of Levin and Blanck,[24] increase the ability of calmodulin to bind calcium and subsequently enhance respiratory burst. This interaction should be irreversible, so that temporary depression of neutrophil function after desflurane exposure might depend on protein synthesis leading to restoration of calmodulin with a normal affinity for calcium. In contrast, halothane or enflurane might decrease the ability of calmodulin to bind calcium and should therefore lead to an immediately reversible inhibition of respiratory burst.

The clinical relevance of impairment of neutrophil function cannot be deduced as our experimental design was not suitable for quantifying clinical effects.

# Heterogeneous effects of protamine on human mast cells and basophils

V. PATELLA, A. CICCARELLI, B. LAMPARTER-SCHUMMERT, A. DE PAULIS, M. ADT AND G. MARONE

## Summary

To investigate the mechanisms of anaphylactoid reactions to protamine, we have examined the *in vitro* effects of increasing concentrations of protamine ($10^{-6}$–$3\times10^{-4}$ mol litre$^{-1}$) on the release of preformed (histamine and tryptase) and *de novo* synthesized (peptide leukotriene $C_4$ ($LTC_4$) or prostaglandin $D_2$ ($PGD_2$)) mediators from human basophils and mast cells isolated from lung parenchyma, heart, skin and synovial tissues. Protamine $10^{-6}$–$3\times10^{-4}$ mol litre$^{-1}$ induced release of histamine, but not *de novo* synthesis of $LTC_4$ from basophils. At concentrations from $10^{-6}$ to $3\times10^{-4}$ mol litre$^{-1}$ it induced histamine release from human heart (mean 6.5 (SEM 1.5) %), skin (17.7 (4.1) %) and to a lesser extent from synovial mast cells, but not from lung mast cells. Protamine also caused the release of tryptase from heart mast cells (12.8 (3.2) μg/$10^7$ cells), but did not induce *de novo* synthesis of $LTC_4$ and $PGD_2$ from lung and skin mast cells. In these experiments cross-linking of IgE by anti-IgE caused release of $LTC_4$ or $PGD_2$ from human basophils or mast cells. These results demonstrate that protamine acted as an incomplete secretagogue, causing the release of preformed mediators from human basophils and mast cells. (*Br. J. Anaesth.* 1997; **78**: 724–730).

**Key words**
Allergy. Histamine. Pharmacology, protamine.

Protamine sulphate is a basic protein extracted from fish sperm heads.[1] The use of i.v. protamine to reverse heparin anticoagulation has increased in the past decade with the advent of cardiopulmonary bypass technology, cardiac catheterization, haemodialysis and leukapheresis.[2–6] However, protamine may be a major cause of morbidity and mortality in these procedures.[2,4,7–10] During the past decade, reports of adverse reactions associated with i.v. protamine (rash, urticaria, bronchospasm, hypotension and increased pulmonary artery pressure) have also increased.[2–6]

The mechanism(s) by which protamine produces adverse reactions is still not completely understood. It has been suggested that they are caused by complement activation,[5,11,12] inhibition of serum carboxypeptidase,[13] thromboxane production[14,15] and anti-protamine IgE antibody via type I immediate hypersensitivity reactions.[26] It has also been suggested that protamine induces or potentiates histamine release from human basophils and mast cells.[16–18]

Techniques are now available to isolate large numbers of mast cells from human lung parenchyma,[19] heart,[20] skin[21] and synovial tissues.[22] These techniques have led to the demonstration that human basophils and mast cells isolated from different anatomical sites vary markedly in their morphological, biochemical and functional responses.[19–25] These cells differ with respect to the releasing activity of various stimuli and release of different preformed (histamine and tryptase) and *de novo* synthesized mediators (peptide leukotriene $C_4$ ($LTC_4$) and prostaglandin $D_2$ ($PGD_2$)).[26]

Preliminary evidence suggests that human basophils and mast cells may also vary in their histamine releasing capacity when challenged with general anaesthetics. For example, thiopentone activates skin mast cells[24] but not human basophils. It should be emphasized that previous studies have focused on the *in vitro* histamine releasing capacity of protamine[16–18] but have not evaluated its possible effects on *de novo* synthesis of chemical mediators.

To investigate the mechanisms of anaphylactoid reactions to protamine, we have tested *in vitro* to see if protamine induces the release of preformed and *de novo* synthesized mediators from human basophils and mast cells isolated from human heart, lung parenchyma, skin and synovial tissues.

## Materials and methods

### REAGENTS

The following were purchased: 60% $HClO_4$ (Baker Chemical Co., Deventer, The Netherlands); piperazine-N,N'-bis (2-ethanesulphonic acid), hyaluronidase, collagenase type II, chymopapain, elastase type I, synthetic $PGD_2$, (Sigma Chemical Co., St Louis, MO, USA); Hanks balanced salt solution (HBSS) and fetal calf serum (FCS) (Gibco,

Grand Island, NY, USA); deoxyribonuclease I and pronase (Calbiochem, La Jolla, CA, USA); RPMI 1640 with Hepes buffer 25 mmol litre$^{-1}$, Eagle's minimum essential medium (Flow Laboratories, Irvine, Scotland); Percoll (Pharmacia Fine Chemicals, Uppsala, Sweden); protamine chlorhydrate (Roche SpA, Milan, Italy); ($^3$H)-LTC$_4$ 39.3 Ci mmol$^{-1}$ and ($^3$H)-PGD$_2$ 210 Ci mmol$^{-1}$ (New England Nuclear, Boston, MA, USA). Rabbit anti-human-Fc$\varepsilon$ antibody was kindly donated by Drs Teruko and Kimishige Ishizaka (La Jolla Institute for Allergy and Immunology, La Jolla, CA, USA). The rabbit anti-PGD$_2$ antibody was a generous gift from Dr L. M. Lichtenstein (The Johns Hopkins University, Baltimore, MD, USA). The rabbit anti-LTC$_4$ was kindly provided by Dr E. J. Kusner (Zeneca, Wilmington, DE, USA).[27] The tryptase radioimmunoassay kit (Pharmacia Tryptase RIACT 50, Pharmacia Diagnostics AB, Uppsala, Sweden) was kindly donated by Kabi Pharmacia SpA (Milan, Italy).

### BUFFERS

The Pipes buffer used in these experiments was a mixture of Pipes 25 mmol litre$^{-1}$, NaCl 110 mmol litre$^{-1}$, KCl 5 mmol litre$^{-1}$, pH 7.37, referred to as "P". P2CG contains, in addition to P, CaCl$_2$ 2 mmol litre$^{-1}$ and glucose 1 g litre$^{-1}$ [28]; pH was titrated to 7.4 with sodium bicarbonate. PGMD is: MgCl$_2$•6H$_2$O 0.25 g litre$^{-1}$, DNase 10 mg litre$^{-1}$ and gelatine 1 g litre$^{-1}$ in addition to P, pH 7.37.

### HISTAMINE RELEASE FROM HUMAN BASOPHILS

Informed consent was obtained from all subjects and approximately 50 ml of blood were obtained and diluted into a final concentration of EDTA 0.008 mol litre$^{-1}$ and 1.1% Dextran 70.[26] The procedures for isolation of peripheral blood basophils and *in vitro* mediator release have been described in detail elsewhere.[29] The cell-free supernatant was assayed for histamine with an automated fluorometric technique.[29] Net percentage release was calculated by subtracting histamine released spontaneously from unstimulated samples (mean 3.6 (SEM 0.9) %) from total histamine released from cell samples lysed with 2% perchloric acid.[29] The difference between replicate histamine measurements was less than 10%.

### ISOLATION AND PARTIAL PURIFICATION OF HUMAN HEART MAST CELLS (HHMC)

The heart tissue used in this study was obtained from patients (36–65 yr) undergoing heart transplantation at the Deutsches Herzzentrum, Berlin, mostly for cardiomyopathy. The explanted heart was immersed immediately in cold (4 °C) cardioplegic solution, shipped to Naples by air (4 °C) and processed within 5–18 h of removal. Fat tissue, large vessels and pericardium were removed from the heart (100–400 g). The tissue was minced finely into 2–5-mm fragments, suspended in P buffer (10 ml/g of wet tissue) and washed three times by centrifugation (the first time 150×$g$, 4 °C, 8 min and twice at 150×$g$, 22 °C, 8 min). The heart fragments were filtered through a 150-μm pore Nytex cloth (Tetko, Inc., Elmsford, NY, USA) and incubated for 15 min at 37 °C under constant stirring in P buffer containing 10 mg collagenase/g of wet tissue.[20 28] Three additional cycles of enzymatic digestion were performed, with a new preparation of collagenase each time. After the last enzymatic digestion, the cell suspension was centrifuged (150×$g$, 22 °C, 8 min) and filtered first through a 150-μm pore Nytex cloth and then through a 60-μm pore Nytex cloth to remove large particles and large cells (mostly myocytes). Lastly, cells were washed twice in PGMD (P 25 mmol litre$^{-1}$, NaCl 110 mmol litre$^{-1}$, KCl 5 mmol litre$^{-1}$, Mg 1 mmol litre$^{-1}$, gelatin 1 g litre$^{-1}$, DNase 20 mg litre$^{-1}$; pH 7.37) by centrifugation at 150×$g$, 22 °C for 8 min. Cell pellets were resuspended in 250 ml of P buffer containing 2% BSA and centrifuged (25×$g$, 22 °C, 2 min) to remove sedimented myocytes.[18] Myocytes (>100 μm long) were pelleted and discarded; supernatants containing endothelial cells, fibroblasts and mast cells were then collected and centrifuged (150×$g$, 22 °C, 8 min). At this stage of purification, Alcian blue-positive cells amounted to <1% of the total cells. HHMC were partially purified by flotation through a discontinuous Percoll gradient prepared by mixing 9 parts Percoll and 1 part 10×P solution. This mixture was then diluted with isotonic P to give Percoll concentrations of 40, 50, 60, 70, 80 and 90%. The cell suspension was overlaid on the Percoll gradient in 50-ml polypropylene tubes and the mixture centrifuged at 350×$g$, 22 °C, for 20 min. The cells found at the interface between the 60–70% and 70–80% fractions were removed and washed twice with P. Mast cells in these populations ranged from 0.1 to 16%, with an average of 14.3 (2.4) %. The enzymatic dispersion of tissue yields ranged between 2 and 6×10$^4$ mast cells per gram of heart tissue.

### PURIFICATION OF HUMAN LUNG MAST CELLS (HLMC)

Human lung tissue (20–80 g) was obtained from patients undergoing thoracotomy and lung resection, mostly for lung cancer. General anaesthesia was induced using the following drugs: droperidol with fentanyl and atropine (premedication); droperidol with fentanyl, thiopentone, suxamethonium and pancuronium (anaesthesia). Lung parenchymal mast cells were isolated as described previously.[19] This technique yielded between 3 and 8×10$^5$ mast cells/g of lung tissue, and purities ranged between 1% and 8%.[19]

### PURIFICATION OF HUMAN SKIN MAST CELLS (HSMC)

Skin (15–65 g) was obtained from either mastectomies for breast cancer or elective cosmetic surgery procedures. General anaesthesia was induced using the following drugs: thiopentone, pancuronium, atropine, fentanyl, ethrane or fluorane. Tissue was placed immediately in Eagle's MEM at 4 °C and used within 1 h. HSMC were isolated as described previously.[21 24] This technique yielded between 1 and $7\times10^5$ mast cells/g of wet tissue, and purities ranged between 1% and 4%.

### PURIFICATION OF HUMAN SYNOVIAL MAST CELLS (HSYMC)

Synovial tissue (22–35 g) used in this study was obtained from patients (27–66 yr) with osteoarthritis or rheumatoid arthritis, undergoing synovectomy at the Division of Orthopaedic Surgery. Extradural anaesthesia was induced with mepivacaine i.v. and atropine, fentanyl and benperidol were given systemically. Resected joint tissue was placed immediately in Eagle's MEM at 4 °C and processed within 2 h of removal using a technique described recently.[22] Fat, cartilage and fibrous tissue were removed, and the tissue was minced finely with scissors into 2–5-mm fragments, suspended in P buffer (10 ml/g of wet tissue) and washed twice by centrifugation at $150\times g$ for 8 min at 4 °C and then at 22 °C. The minced synovium was incubated for 45 min at 37 °C in a shaking water bath with chymopapain 1 mg $ml^{-1}$ and pronase 0.5 mg $ml^{-1}$ in 1 ml of Tyrode's buffer/g synovial tissue. Fragments of remaining tissue were digested for another 45 min at 37 °C with collagenase 1 mg $ml^{-1}$. The resulting cell suspensions were pooled, filtered twice through 200-μm pore Nytex cloth (Tetko, Elmsford, NY, USA), centrifuged at $200\times g$, 22 °C for 8 min, and washed twice with P buffer. Cells were washed three times in P and resuspended in P2CG. This technique yielded between 1 and $9\times10^5$ mast cells/g of wet tissue, and purities ranged between 1% and 8%.

### MEDIATOR RELEASE FROM HUMAN MAST CELLS

Mast cells (approximately $3\times10^4$ cells per tube) were resuspended in P2CG, and 0.3 ml of the cell suspension was placed in 12×75 mm polyethylene tubes and warmed to 37 °C; 0.2 ml of each pre-warmed releasing stimulus was added, and incubation was continued at 37 °C for 30 min.[26 29] At the end of this step, the reaction was stopped by centrifugation at $1000\times g$, 22 °C for 2 min, and the cell-free supernatants were stored at −70 °C for subsequent assay of histamine, tryptase, $LTC_4$ and $PGD_2$ content. The cell-free supernatants were assayed for histamine with an automated fluorometric technique.[29] To calculate histamine release as a percentage of total cellular histamine, "spontaneous" release from mast cells (2–12% of the total cellular histamine) was subtracted from both numerator and denominator. The total histamine content in mast cells was obtained by cell lysis with 8% $HClO_4$.[24–26] All values are based on the means of duplicate or triplicate determinations. Replicates differed from each other by less than 10% in histamine content.

### RIA OF TRYPTASE, $LTC_4$ AND $PGD_2$

Total tryptase content was assessed by lysis induced by incubating cells with 0.1% of Triton X-100. Tryptase was analysed by a solid-phase radioimmunoassay (Pharmacia Tryptase RIACT 50).[20 26] $PGD_2$ was analysed on 100-μl fractions obtained from the supernatant fluids. The samples were stored at −70 °C. $LTC_4$ and $PGD_2$ were analysed by RIA within 18 h of the experiment to minimize degradation of the compounds.[23]

### STATISTICAL ANALYSIS

Results are mean (SEM). Statistical analysis was performed by two-way non-parametric analysis of variance (Friedman's chi-square test). The extended Tukey test was used for multiple comparisons. The level of statistical significance was $P<0.05$.[30]

## Results

In the first series of experiments we evaluated the effects of increasing concentrations ($10^{-6}$–$3\times10^{-4}$ mol $litre^{-1}$) of protamine on histamine release from human basophils. Protamine caused concentration-dependent histamine release from basophils from 11 normal donors (table 1). In one experiment, protamine released less then 5% of histamine content but in all other experiments release varied from 5% to 26%. The release caused by protamine reached a plateau between $10^{-5}$ and $3\times10^{-5}$, with less release above these concentrations. Anti-IgE, used as a

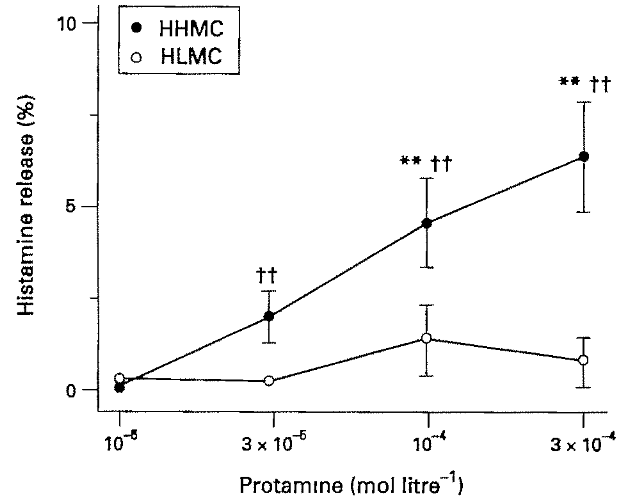

*Figure 1* Effect of increasing concentrations of protamine on release of histamine from HHMC and HLMC. Results are mean (SEM) of 11 (HHMC) or nine (HLMC) different donors. Error bars are not shown when graphically too small $^{**}P<0.01$ compared with spontaneous release; $^{\dagger\dagger}P<0.01$ compared with histamine release induced by protamine from HLMC.

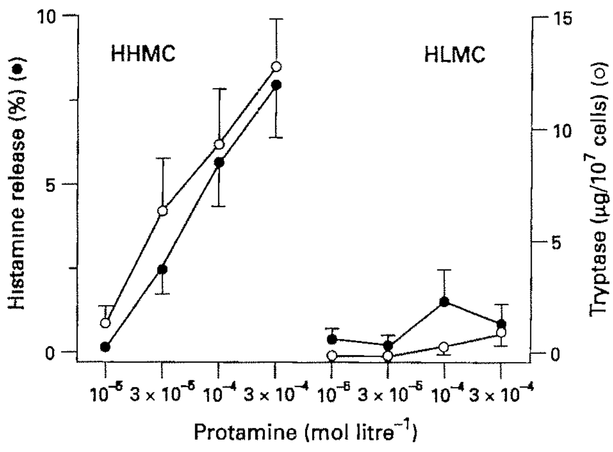

*Figure 2* Effect of increasing concentrations of protamine on histamine and tryptase release from HHMC and HLMC. Results are mean (SEM) of four (HHMC) or five (HLMC) different donors. Error bars are not shown when graphically too small.

positive control in these experiments, induced 28.9 (5.4) % of histamine release. There was no correlation between the maximum release caused by protamine and anti-IgE ($r_s$=0.01; ns). Cell viability in the presence of protamine was always ≥95% as detected by trypan blue exclusion.[28]

In the second series of experiments we compared the effect of protamine on histamine release from HHMC and HLMC. Protamine $10^{-5}$– $3\times10^{-4}$ mmol litre$^{-1}$ induced histamine release from HHMC in a concentration-dependent manner (fig. 1) with maximum release between 3% and 17% (8.8 (1.4) %) ($P<0.01$ compared with spontaneous release). In none of nine HLMC preparations did protamine induce the release of more than 5% of histamine content (fig. 1).

In view of the functional heterogeneity of human mast cells isolated from different anatomical sites,[20] [22–26] [28] we evaluated the effects of increasing concentrations ($10^{-5}$–$3\times10^{-4}$ mmol litre$^{-1}$) of protamine on histamine release from mast cells from skin and synovial tissues. These concentrations of protamine induced histamine release from HSMC (table 2) and to a lesser extent from HSyMC (table 3). The maximum release varied between 7% and 25% (HSMC) and 12% and 13% (HSyMC).

Tryptase is a neutral protease that is a selective marker for mast cells.[31] The secretory granules of all mature human mast cells contain large amounts (approximately 24.2 (4.3) μg/$10^6$ HHMC of tryptase).[20] [22] We investigated if activation of HHMC with protamine caused release of tryptase in addition to histamine. Tryptase was released in parallel with histamine from HHMC whereas protamine did not induce release of histamine and tryptase (<5%) from HLMC in three experiments (fig. 2).

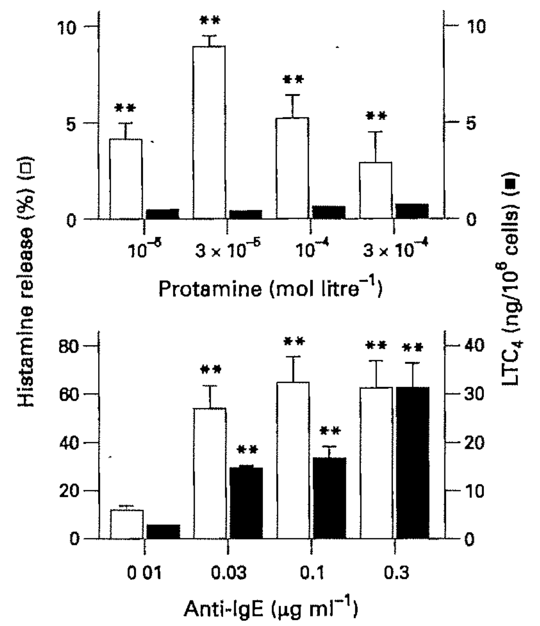

*Figure 3* Effect of increasing concentrations of protamine and anti-IgE on release of histamine and LTC$_4$ from human basophils. Results are mean (SEM) of three experiments. Error bars are not shown when graphically too small. **$P<0.01$ compared with spontaneous release.

Different experimental models have shown that some of the adverse effects of protamine are caused by generation of eicosanoids.[32,33] We therefore compared production of the newly formed lipid mediators from human basophils and mast cells activated by protamine $10^{-5}$–$3 \times 10^{-4}$ mmol litre$^{-1}$ and anti-IgE $10^{-2}$–$3 \times 10^{-1}$ µg ml$^{-1}$. In this group of experiments protamine induced concentration-dependent release of histamine from basophils, but did not stimulate *de novo* synthesis of LTC$_4$ by these cells (fig. 3). Anti-IgE stimulated release of large amounts of LTC$_4$. Protamine also did not induce *de novo* synthesis of PGD$_2$ or LTC$_4$ from HHMC and HSMC, whereas anti-IgE stimulated the release of these eicosanoids (data not shown).

## Discussion

Our results indicate that protamine is an incomplete secretagogue inducing only release of preformed mediators (histamine and tryptase) from human basophils and mast cells without stimulating *de novo* synthesis of eicosanoids. Protamine activated not only peripheral blood basophils, but also mast cells isolated from human heart, skin and synovial tissues, but not from lung parenchyma.

Intravascular administration of high concentrations of protamine is used increasingly to reverse heparin anticoagulation during cardiac catheterization,[4] cardiothoracic and vascular surgical procedures[34,35] and after dialysis[36] and leukapheresis.[37] I.v. protamine can cause acute reactions such as rash, urticaria, bronchospasm, hypotension, cardiovascular collapse, pulmonary hypertension and even death.[2,4,7-9] These adverse reactions are thought to be caused by multiple mechanisms, including anaphylactic[2-6] and anaphylactoid reactions.[11-14,16-18] Intravascular administration of protamine causes rapid and massive exposure of basophils to this agent. It is therefore likely that the release of histamine from peripheral blood basophils might at least partly explain some of the adverse effects of protamine in some patients.

Intravascularly administered compounds rapidly expose circulating basophils and tissue mast cells to very high concentrations that tend to decline according to their pharmacokinetics. Thus we investigated the effects of a wide range of concentrations of protamine which must include concentrations reached during intravascular administration of the compound. The percentage of histamine release from basophils caused by protamine varied greatly from donor to donor, presumably because of the influence on basophil releasibility.[19,23,38] This may partly explain the wide variability of protamine-induced adverse effects in patients given this drug intravascularly.[6] At first sight, the bell shape of the dose–response curve of protamine on release of histamine from basophils might be surprising. However, other stimuli (anti-IgE, antigens, etc.) can produce a similar dose–response curve.[20]

Although it has been demonstrated in different experimental models that the adverse reactions to protamine are to some extent caused by synthesis of eicosanoids and other lipid mediators,[32,33] protamine did not induce release of LTC$_4$ and PGD$_2$ from human basophils and mast cells *in vitro*. Possibly *in vivo* protamine induces the release of lipid mediators from other cells.

Radiocontrast media, which can cause anaphylactoid reactions, also act as incomplete secretagogues on human basophils and mast cells[26] and pretreatment with histamine H$_1$ and H$_2$ receptor antagonists reduces the incidence and severity of adverse reactions to these agents.[39] In the light of our results, it might be appropriate to investigate if these antagonists also reduce the incidence of anaphylactoid reactions to protamine.

Protamine caused a concentration-dependent release of tryptase from HHMC, HSMC and HSyMC. This neutral protease, present in the cytoplasmic granules of all human mast cells,[20,22,31] can activate complement leading to the formation of anaphylatoxins (C3a and C5a).[40] Complement activation and C3a formation can occur during *in vivo* administration of protamine[11-14] and tryptase release from mast cells might therefore contribute, as an amplification factor, to the pathogenesis of the generalized reactions to protamine, through activation of the complement system. Tryptase has a longer half-life than histamine in plasma.[31] Therefore, it may be useful to measure plasma concentrations of tryptase in order to identify adverse reactions caused by protamine in humans.

Our results showed that protamine can induce release of vasoactive and proinflammatory mediators from HHMC *in vitro*. Coronary artery spasm, hypotension and shock can occur during intravascular administration of protamine.[8,9] Mast cells have been demonstrated clearly within human heart tissue,[20,28] around coronary vessels and in the shoulder region of atherosclerotic human coronary vessels.[41] During intravascular administration of protamine, cardiac mast cells are likely to be exposed to high concentrations and our findings suggest that *in vivo* they can thus be activated to release histamine, tryptase and possibly other mediators. Histamine exerts significant cardiovascular effects in humans[42] and vasoactive mediators released locally from coronary and cardiac mast cells might therefore contribute to the pathogenesis of severe adverse reactions to protamine.

Unlike HHMC and HSMC, HLMC were not activated by protamine *in vitro*. However, transient increases in pulmonary artery pressure are frequent when protamine is administered i.v.[7 14] It is therefore possible that the pulmonary reactions to protamine involve alternative mechanisms such as direct activation of basophils, tryptase-mediated formation of anaphylatoxins that in turn activate C5a receptors on HSMC[18 23] and HHMC,[20] or other unknown mechanisms. Our results were obtained with preparations of mast cells isolated from different tissues of patients receiving several drugs before and during surgical procedures. Consequently, we cannot exclude the possibility that some of the heterogeneous effects of protamine on the release of mediators from mast cells isolated from different tissues might be influenced by the *in vivo* treatment of the cell donors.

In conclusion, these findings suggest that protamine selectively activated different types of human mast cells and basophils, acting as an incomplete secretagogue. These results are of interest for several reasons. They contribute to a better understanding of the pathogenesis of immediate generalized reactions caused by rapid injection of protamine and they also suggest that anti-$H_1$ and anti-$H_2$ blockers might be useful in attenuating anaphylactoid reactions to this substance. Finally, they indicate that measurements of plasma tryptase might be useful to identify adverse reactions.

## Acknowledgements

This work was supported in part by grants from the C.N.R. (Targeted Project F.A.T.M.A.; Prevention and Control of Disease Factors; SP2 No. 94.00607.PF41 and 95.00856.PF.41) and the M U.R.S.T. (Rome, Italy). This work was performed within the frame of the EU ENDA Programme BIOMED 1, CT 93–1661. We thank Drs G. Aliperta and F. Tatangelo for supplying lung and skin tissue specimens.

REVIEW ARTICLE

# Glutamate: a role in normal brain function, anaesthesia, analgesia and CNS injury

M. J. HUDSPITH

Glutamate is the major excitatory amino acid (EAA) neurotransmitter in the central nervous system (CNS).[78] EAA neurones and synapses are distributed widely throughout the CNS,[36 231] but they are concentrated particularly in the hippocampus,[91] the outer layers of the cerebral cortex[91] and the substantia gelatinosa of the spinal cord.[194] Within these regions EAA play key roles in physiological processes including learning and memory (and hence awareness under anaesthesia), central pain transduction mechanisms and pathological processes such as excitotoxic neuronal injury which follows CNS trauma or ischaemia. Thus an understanding of the role of EAA in the CNS is relevant to normal higher brain function and to anaesthesia, analgesia and intensive care.

A broad spectrum of pharmacological agents which alter EAA-mediated neurotransmission are already available and many more are under development. These include: (i) drugs that specifically target the release of EAA (e.g. the novel antiepileptic drugs felbamate and lamotrigine), (ii) drugs that modify the interactions of EAA with specific receptors (e.g ketamine) and (iii) volatile and i.v. anaesthetic agents which may have a common mechanism of action that, at least in part, involves EAA-mediated neurotransmission. To understand the potential applications of these agents it is necessary to consider first how EAA act at the level of the synapse and the individual neurone. To do so involves a brief outline of EAA receptor subtypes and how their activation affects the postsynaptic neurone. It may then be possible to explain how EAA and their receptors are involved in cognition, anaesthesia, analgesia and neurointensive care and therefore to provide a framework to assess the possible clinical applications of drugs which modify EAA-mediated neurotransmission.

## Excitatory amino acid neurotransmission

A diagrammatic representation of an EAA synapse comprising a presynaptic nerve terminal and a postsynaptic neurone expressing multiple EAA receptor subtypes is shown in figure 1 and described first in terms of presynaptic events and then activation of postsynaptic receptors.

### PRESYNAPTIC EVENTS

Glutamate, synthesized by the deamination of glutamine or via the tricarboxylic acid cycle, is released into the synaptic cleft in response to depolarization of the presynaptic nerve terminal. The release of glutamate from presynaptic terminals (and that of other neurotransmitters), is a $Ca^{2+}$-dependent process regulated by multiple types of $Ca^{2+}$ channel. N-type and P-type $Ca^{2+}$ channels are probably the most important determinants of exocytotic neurotransmitter release from presynaptic nerve terminals throughout the CNS[55] although other channel types (such as Q and R) may also be involved. Importantly, different $Ca^{2+}$ channel types may be involved in the exocytotic release of neurotransmitter from different neurones within the CNS and from different sites in individual neurones.[55] After release of glutamate, binding to specific receptor types described in the following section determines the postsynaptic response.

In common with many other central neurotransmitter systems,[88] the actions of glutamate within the synaptic cleft are terminated by high affinity sodium-dependent uptake. Glutamate transporters are localized in both pre- and postsynaptic neuronal elements together with glial cells.[182] Three, or possibly four, glutamate transporters have been characterized[64 96 164 201] (for a recent review see Malandro and Kilberg[128]), each of which are transmembrane proteins of approximately 60–70 kDa size with $K_m$ values for glutamate in the low micromolar range.

### EXCITATORY AMINO ACID RECEPTORS

Two main subgroups of EAA receptors have been identified: *ionotropic* and *metabotropic* receptors.[191 223] Ionotropic glutamate receptors (*i*Glu-receptors) are so named because such receptors are ligand-operated ion channels (LOC) and a change in membrane permeability to specific cations occurs

(*Br. J. Anaesth.* 1997; **78**: 731–747).

**Key words**
Protein, amino acids, glutamate. Brain, glutamate. Nerve, neurotransmitters. Pain. Anaesthesia, general.

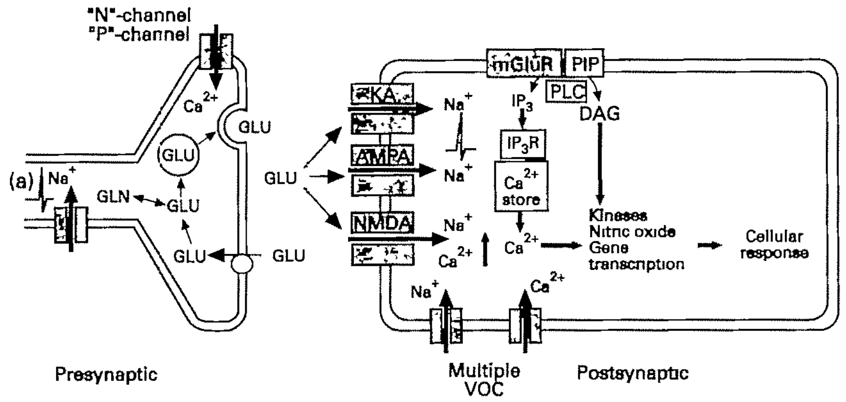

*Figure 1* Schematic representation of an excitatory amino acid (EAA) synapse within the CNS. Glutamate is released from the presynaptic nerve terminal in response to depolarization-dependent $Ca^{2+}$ entry through "N-" or "P-" type voltage-operated $Ca^{2+}$ channels. Glutamate within the synaptic cleft can bind to ionotropic and metabotropic glutamate receptors (mGluR) on the postsynaptic neurone: individual neurones may express multiple glutamate receptor subtypes. Receptor activation evokes a cellular response via increases in intracellular $Ca^{2+}$ and activation of protein kinases. GLU=glutamate; NMDA=*N*-methyl-D-aspartate; KA=kainate; GLN=glutamine; AMPA=α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate; PIP=phosphatidyl-inositol-4,5-bisphosphate; PLC=phospholipase C; $IP_3$=inositol-1,4,5-trisphosphate; $IP_3R$=$IP_3$ receptor; DAG=diacylglycerol; VOC=voltage-operated ion channel; (a)=depolarization and action potential generation.

within a few milliseconds of agonist binding (see below). The *i*Glu-receptor family can be classified pharmacologically according to activation by specific agonists into three subtypes: *AMPA* receptors (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate), *KA* receptors (kainate) and *NMDA* receptors (*N*-methyl-D-aspartate).

The family of metabotropic glutamate receptors (*m*Glu-receptors; for clarity, *m*GluR in fig. 1) are receptors linked to G-proteins that modulate intracellular second messengers such as inositol phosphates and cyclic nucleotides. Their classification is complicated by the lack of ligands showing selectivity for individual *m*Glu-receptor subtypes. However eight *m*Glu-receptor subtypes have been identified by molecular biological techniques (for reviews see Miller,[139] Nicoletti and colleagues,[150] and Pin and Duvoisin[163]); all are members of the 7-transmembrane receptor superfamily and can be further classified according to sequence homology and signal transduction pathways into three groups (see table 1). Whereas activation of *i*Glu-receptors results in a response (i.e. membrane depolarization) within a few milliseconds of agonist binding, the G-protein coupled *m*Glu-receptors evoke changes in neuronal excitation on a time scale of hundreds of milliseconds to seconds.

In contrast to the 7-transmembrane *m*Glu receptor, ionotropic EAA receptors are composed of multiple subunits. At least 16 genes encoding *i*Glu receptor subunits have been characterized (see table 2: for reviews see Seeburg[193] and Sucher and colleagues[203]), and some of these genes (notably those encoding the NMDAR1[56] and GluR1-GluR4[197] subunits) undergo RNA editing producing multiple splice variants. Accordingly, multiple variants of glutamate receptor subtypes are expressed throughout the CNS and can be identified using molecular biological techniques.[83 206 232] However, for the purpose of this review the pharmacological classification listed above will be used. The roles of the *i*Glu-receptor family in systems of relevance to anaesthesia and analgesia are currently better characterized than those of the *m*Glu-receptor family; much of the following therefore concentrates on *i*Glu-receptor mediated mechanisms of neurotransmission.

### *Ionotropic receptors*

When activated, *i*Glu-receptors undergo a conformational change that results in the opening of their

respective ligand-operated channel (LOC). The gating properties and ion flux through *i*Glu-receptor LOC may be modified by the binding of other ligands to modulatory binding sites separate from the glutamate binding site. Activation of *i*Glu-receptors causes transmembrane flux of cations resulting in depolarization of the postsynaptic membrane. Subsequent postsynaptic events may be a direct consequence of cation entry and/or opening of voltage-operated ion channels and further cation entry (see fig. 1).

*AMPA receptors.* AMPA receptor channels consist of homomeric or heteromeric assemblies of GluR1-GluR4 subunits[193] (see table 2); the resultant receptor channel is primarily a $Na^+$ channel with rapid kinetics of activation and deactivation. Such a kinetic profile renders AMPA receptors ideal for mediation of fast excitatory neurotransmission throughout the CNS, and their generally very low $Ca^{2+}$ permeability ensures that this glutamate-activated excitation does not trigger longer term biochemical processes evoked by an increase in intracellular $Ca^{2+}$ concentrations.

All AMPA receptors show onset, offset and desensitization time courses in the order of a few milliseconds, although current:voltage relationships and cation permeability are specifically determined by subunit composition. For example, the normally cation impermeable AMPA receptor channel may permit $Ca^{2+}$ entry if the GluR2 is absent,[81] although whether AMPA receptor-mediated $Ca^{2+}$ entry has physiological relevance is unclear. A second binding site for 2,3 benzodiazepines attenuates the response of the channel to prolonged agonist stimulation and 2,3 benzodiazepines act as non-competitive AMPA antagonists.[51]

*Kainate receptors.* The neurotoxin, kainate (KA), binds to a specific high affinity KA receptor (identified in sensory ganglia) and activates a rapidly desensitizing $Na^+$ channel[82] with similar kinetics to the AMPA receptor. High affinity kainate receptors can be generated *in vitro* from multimeric assemblies of GluR5–7 and KA1 or KA2 subunits[193] (table 2) but again, precise kinetic variables of activation and inactivation are determined by subunit composition. Kainate also binds to the AMPA receptor with a lower affinity resulting in persistent, non-desensitizing activation of the AMPA receptor channel and this effect may overshadow transient high affinity KA receptor responses in central neurones.[193] Currently the distinction between AMPA and kainate receptors is somewhat blurred dependent on classification according to gating or ligand binding, however, activation of either receptor subtype by the endogenous ligand glutamate results in rapid, although transient, depolarization of the postsynaptic membrane.

*NMDA receptors.* The NMDA receptor channel preferentially permits $Ca^{2+}$ entry[119] and the kinetics of this channel are much slower than those of the two preceding types of *i*Glu-receptor with channel opening persisting for several tens or hundreds of milliseconds. NMDA receptors can be reconstituted *in vitro* as heteromeric combinations of the NR1 subunit and one of four NR2 subunits (NR2A-D)[193 203] (table 2). The NR1 subunit common to all NMDA receptors exists in at least eight splice variants,[232] and this together with the four NR2 subunits provide the potential for a vast array of NMDA receptor subtypes to exist within the CNS. As with each of the ionotropic glutamate receptor classes, subunit composition determines the (complex) gating properties of the channel, however caution has been recommended in comparing the pharmacological properties of recombinant NMDA receptors with those of native neurones[203] and no attempt is made in the following to differentiate between NMDA receptor subtypes.

The gating properties of the NMDA receptor channel are complex and subject to modulation at several different sites (fig. 2). In addition to its binding site for EAA such as NMDA or glutamate, the receptor has a second binding site for glycine which facilitates the actions of glutamate or NMDA.[93] However, in the resting (i.e. non-depolarized) state, the NMDA receptor channel is blocked by $Mg^{2+}$ ions at a site deep within the channel itself[133 152] and binding of NMDA or glutamate to the agonist binding site, even in the presence of glycine, does not result in $Ca^{2+}$ entry through the postsynaptic

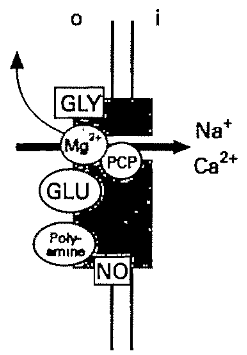

*Figure 2* Schematic representation of the NMDA receptor complex. In the non-depolarized neuronal membrane, binding of glutamate and glycine does not result in $Ca^{2+}$ entry while the ion channel remains blocked by $Mg^{2+}$. Depolarization removes the $Mg^{2+}$ block enabling cation entry. Cation flux is inhibited by agents binding to the phencyclidine site within the ion channel and modulated by agents interacting with the polyamine and redox sites. i= Intracellular; o=extracellular; GLU=glutamate; GLY=glycine; PCP=phencyclidine; NO=redox site.

membrane. Depolarization of the membrane removes the $Mg^{2+}$-mediated channel blockade and $Ca^{2+}$ flux through the channel can then occur. Calcium entry through the NMDA receptor channel can also be modulated by micromolar concentrations of $Zn^{2+}$ ions[132,220] which inhibit channel opening time in a voltage-independent manner.[134] The NMDA receptor channel is subject to further modulation by agents such as dizolcipine (MK-801) that bind to a site (phencyclidine binding site) within the channel itself[92]; binding to this site is enhanced significantly when the channel is activated and such agents (which include the dissociative anaesthetics ketamine and phencyclidine) are known as *open-channel blockers*. Outside the channel are further modulatory sites: these include a polyamine binding site[175] and a redox site[110] where sulphydryl groups of the subunits may interact with nitric oxide (NO) derivatives to modify channel function.

The slow kinetics of dissociation of glutamate from its agonist site (time constants of decay in the order of tens or hundreds of milliseconds), and the necessity of coincident membrane depolarization to permit channel opening enable the NMDA receptor to function as a molecular detection device for near coincident pre- and postsynaptic depolarization. The resultant increase in intracellular $Ca^{2+}$ may trigger sequences of molecular events that lead to longer term changes in neuronal function.

## Excitatory amino acids and anaesthesia

General anaesthetic agents have a broad spectrum of actions; they modify both inhibitory and excitatory neurotransmission at presynaptic and postsynaptic loci within the CNS[67,108,166,176]; nevertheless their precise mode of action remains uncertain and undoubtedly they interact with multiple neurotransmitter systems by a variety of mechanisms.[115]

Attempts have been made to produce "unitary theories of anaesthesia" and one proposed mechanism, common to general anaesthetic action is that of potentiation of the inhibitory neurotransmitter γ-amino-butyric acid (GABA) at the $\text{GABA}_A$ receptor $\text{Cl}^-$ channel.[67] However, there is a growing body of evidence that general anaesthetic agents also modify EAA-mediated excitatory neurotransmission in the CNS, and this has important implications with regard to the means by which anaesthetics suppress the responses to, and awareness of, noxious stimuli. The evidence for anaesthetic effects on EAA is reviewed below (data summarized in table 3).

## PRESYNAPTIC EFFECTS OF GENERAL ANAESTHETICS

As stated above, the release of EAA neurotransmitters is dependent on $\text{Ca}^{2+}$ entry into nerve terminals through N-type, P-type and possibly other voltage-operated channels in the presynaptic membrane.[55] Voltage-operated $\text{Ca}^{2+}$ channels are themselves a target of general anaesthetic action and the evidence for their inhibition by volatile and i.v. anaesthetics in a variety of neuronal populations has been reviewed recently.[102] Two studies that specifically examined anaesthetic effects on $\text{Ca}^{2+}$ channel subtypes in hippocampal neurones have shown that halothane, enflurane and isoflurane markedly inhibit multiple $\text{Ca}^{2+}$ channel types at clinically relevant concentrations.[106,202] It should be noted that $\text{Ca}^{2+}$ channel sensitivity to general anaesthetics may vary in different neuronal populations as P-type $\text{Ca}^{2+}$ channels were unaffected by isoflurane in cerebellar neurones[76] but may be sensitive to this agent in hippocampal neurones.[202]

Inhibition of $\text{Ca}^{2+}$ channel function would be expected to reduce the release of EAA and several early studies suggested that both volatile anaesthetics[177,178,179] and barbiturates[33,100,140] could decrease the depolarization-evoked release of EAA neurotransmitters from central neurones. Recent studies have confirmed this effect with the demonstration that both isoflurane[109,124] and halothane[124,162] at clinically relevant concentrations (0.5–2 MAC) markedly inhibit release of glutamate from hippocampal neurones in a dose-dependent manner. Furthermore, data demonstrating inhibition by halothane, enflurane and isoflurane of glutamate release[138,190] associated with reduced $\text{Ca}^{2+}$ entry[138] in cerebral cortical nerve terminals strongly suggest that presynaptic inhibition of glutamate release may be a common property of volatile anaesthetic agents.

The specific sodium-dependent glutamate transporters that limit the synaptic duration of EAA by uptake into both neurones and astroglia have been shown not to be sensitive to clinically relevant concentrations of either volatile or i.v. anaesthetics.[149]

## POSTSYNAPTIC EFFECTS OF GENERAL ANAESTHETICS

When postsynaptic effects are considered, it is clear that volatile and i.v. anaesthetic agents have in general, inhibitory effects on the excitatory responses of CNS neurones to exogenously applied EAA agonists (see table 1). Inhibition of each of the *i*Glu-receptor subtypes has been reported by a number of investigators,[14,148,169,188,218,229] however, subtype specific effects on *i*Glu-receptor function have not been consistent. This may reflect the different methodologies used in these studies; most notably this applies to halothane which under different conditions may either inhibit[148,169] or have no effect[162] on hippocampal NMDA receptor and AMPA receptor function.

The data in table 1 demonstrate that general anaesthetic agents apparently share a common property of inhibiting EAA-mediated neurotransmission at several sites within the mammalian CNS. However, the predominant site and nature of the inhibition differs according to the region of the CNS and the anaesthetic agent under investigation. Presynaptically, this may reflect the variations in $\text{Ca}^{2+}$ channel populations responsible for neurotransmitter release[55] and their different sensitivities to anaesthetics in different areas of the CNS.[76,202] When postsynaptic effects are considered, the recent report that anaesthetic agents can have subunit selective actions at glutamate receptors[50] indicates that variations in *i*Glu-receptor subunit composition throughout the CNS[83] may determine the response to anaesthetics in different brain regions.

## IS INHIBITION OF EAA NEUROTRANSMISSION CAUSAL TO ANAESTHESIA?

If inhibition of EAA-mediated neurotransmission causes the anaesthetic state, then specific pharmacological manipulation of EAA neurotransmission should affect anaesthesia induced by other volatile or i.v. agents. This is clearly seen with glutamate antagonists which markedly reduce the MAC for other anaesthetic agents *in vivo*. This has been demonstrated, for example with the non-competitive NMDA antagonists ketamine,[39] phencyclidine[39,189] and MK-801/dizolcipine[107,189], the competitive NMDA antagonists CGS 19755 and D-CPP-ene[40,107] and agents acting at the polyamine site[41] and also the glycine site[121] of the NMDA receptor. The AMPA receptor competitive antagonist NBQX appears to share similar properties.[120] Furthermore, riluzole (a drug inducing a use-dependent block of presynaptic glutamate fibres[123]) has been reported to reduce the MAC for halothane and potentiate barbiturate anaesthesia *in vivo*.[130]

There is thus convincing evidence that a state of anaesthesia is associated with inhibition of EAA neurotransmission throughout the CNS. Significantly, inhibition of spinal cord EAA neurotransmission[34,186,187] could also contribute to anaesthesia (in the sense of ***unresponsiveness to surgical stimuli***) with the demonstration that the MAC for isoflurane in the rat is independent of forebrain integrity[170,171] and that a site of action distal to the brainstem contributes significantly to the anaesthetic effects of isoflurane in the goat.[4,22]

It must be emphasized that anaesthesia induced in humans with glutamate antagonists such as ketamine or phencyclidine differs from that induced by other anaesthetic agents. It is characterized by sedation, hypertonus, amnesia and profound analgesia[54] and has been termed dissociative anaesthesia, referring to a supposed "dissociation of the limbic from the thalamo-neocortical systems".[35] When auditory evoked responses (AER) are used to assess depth of anaesthesia, it is apparent that the effects of ketamine differ from those of the majority of general anaesthetics. Using this technique, volatile agents, propofol, etomidate and barbiturates significantly reduce the amplitude and increase the latency of the early cortical part of the AER,[94] whereas ketamine (in common with opioids and benzodiazepines) has little or no effect on the AER.[192] Further differences between ketamine and other i.v. anaesthetics are apparent when effects on cerebral metabolism are considered. Barbiturates globally depress cerebral metabolism[80] while other i.v. agents (such as propofol, Althesin and etomidate) predominantly depress forebrain metabolism and spare hindbrain metabolism.[38 42 43] In contrast, anaesthetic doses of ketamine have little effect on metabolism in most brain regions but cause a marked increase in metabolism in the hippocampus.[37 44] Enhanced hippocampal metabolism has also been shown with volatile anaesthetics[146 157] although this is accompanied by global inhibition of metabolism in other brain regions.[77 157]

If the increased hippocampal metabolism seen with anaesthetic doses of ketamine is mediated via its action at the NMDA receptor, then similar increases observed with volatile agents may indicate a common mechanism of action. Conversely, the markedly different effects seen with barbiturates, propofol, etomidate and Althesin suggest that actions on EAA neurotransmission may be less significant with these i.v. anaesthetics. The effects of different anaesthetics on cerebral metabolism may reflect the balance between anaesthetic actions on EAA neurotransmission and inhibitory neurotransmitter systems, notably the $GABA_A$ receptor (for reviews see Frank and Lieb[67] and Pocock and Richards[166]). This balance could in turn determine the clinical manifestations of the anaesthetic state induced by each individual agent.

## EAA and memory: is this how anaesthetics prevent recall?

Sub-anaesthetic or sedative doses of general anaesthetics have powerful inhibitory effects on short term memory,[68 143] and the reduction in the transfer of information from the periphery to the cerebral cortex[3] associated with general anaesthesia prevents the recall of intraoperative events. EAA neurotransmission plays a central role in the pharmacology of learning and memory[90 142]; therefore it is important to consider if this absence of memory for intraoperative events is a consequence of inhibition by general anaesthetics of EAA-mediated processes. In order to do so, it is necessary first to provide an overview of the fundamental mechanisms involved in memory at both synaptic and more global levels, and subsequently to review the available data relating to anaesthetic interactions with these systems.

Current theories propose that at the synaptic level, learning and memory are a consequence of long-term potentiation (LTP) of synapses in specific neuronal pathways within the CNS.[19] First described in the hippocampus by Bliss and Lømo in 1973,[20] LTP is a form of synaptic plasticity causing facilitation of neurotransmission which may last for up to several weeks *in vitro*. LTP has been demonstrated subsequently in other regions of the CNS, including the cerebral cortex[8 17] and spinal cord.[165 172] The mechanisms underlying LTP have been investigated extensively and it is clear that EAA play a key role.

This key role for EAA in memory has been confirmed in animal models of learning using the Morris water maze. This tests the ability of the rat to learn the location of a hidden platform in a tank of opaque water in which it is forced to swim.[142] Intracerebroventricular administration of NMDA antagonists impairs the ability of the rat to learn a new location of the platform but not to find a location that was learned previously; importantly, this impairment is associated with disruption of hippocampal LTP *in vivo*.[142] These and similar data from a variety of animal models of learning and memory provide good evidence that "*NMDA receptors are involved in the acquisition of new information but not in its subsequent retrieval or expression*.[142] Similarly, in humans, administration of sub-anaesthetic doses of the non-competitive NMDA antagonists ketamine and phencyclidine causes dose-dependent anterograde amnesia but has no effect on established memory.[9 69]

The hippocampus undoubtedly plays an important role in learning and memory,[199] as is evident in humans from the gross impairment of short term memory in patients with hippocampal lesions, but it does not function in isolation: current concepts of memory propose that the hippocampus functions in concert with neuronal networks of the cerebral cortex. Memory "traces" are thought to be retained briefly in the cortical areas that process incoming information, but hippocampal activation (presumably involving LTP as described above) is essential to establish *new* memory. After hippocampal activation, medial temporal lobe structures direct the consolidation of memories in specific neuronal networks of the neocortex[198 199] where again NMDA-mediated LTP may play a critical role.[137] Activation of specific hippocampal and cortical regions during learning and memory has been confirmed *in vivo* in humans using positron emission tomography studies of cerebral blood flow[181 210] and has led to the development of a model of hemispheric asymmetry for memory encoding and retrieval (HERA) involving large distributed cortical neuronal networks.[208]

The data discussed above provide a mechanistic model for a human memory system consisting of several systems and subsystems.[219] Two separate systems, explicit memory and implicit memory, can be identified readily by psychological tests. The former requires deliberate and conscious retrieval of information and can be assessed by recall and recognition tests, while the latter does not require conscious recall but is manifest as improvement in performance in skill learning or task-completion tests. General anaesthesia by definition inhibits explicit memory of intraoperative events, however, several studies have demonstrated that some forms of implicit memory may still occur during anaesthesia (reviewed in Ghoneim and Block[68]), thereby suggesting that the different systems of memory may be differentially sensitive to anaesthetics. For example, using sub-anaesthetic concentrations of isoflurane it has been shown that implicit memory occurs at concentrations of isoflurane (0.15–0.3 MAC) that impair explicit recall[57]; and when coherent frequency of auditory evoked response is used to assess quantitatively depth of anaesthesia,[143] inhibition of implicit memory requires a greater depth of anaesthesia than does inhibition of explicit recall.

### DOES INHIBITION OF EAA-DEPENDENT NEUROTRANSMISSION SUPPRESS LEARNING AND MEMORY UNDER GENERAL ANAESTHESIA?

To answer this question we need to consider the mechanisms of hippocampal LTP, the best understood synaptic model of memory.[19] A schematic representation of the processes involved in hippocampal LTP is shown in figure 3.

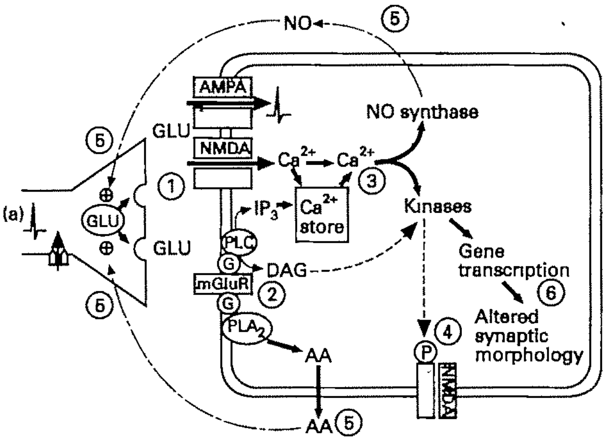

*Figure 3* Schematic representation of the mechanisms involved in hippocampal long-term potentiation (LTP). ① Induction of LTP is dependent on EAA release and NMDA receptor activation resulting in enhanced $Ca^{2+}$ entry into the postsynaptic neurone. ② This $Ca^{2+}$ signal may be supplemented by $Ca^{2+}$ release from inositol 1,4,5-trisphosphate ($IP_3$) gated stores which occurs as a consequence of co-activation of *m*Glu-receptors.[58] ③ The increase in $Ca^{2+}$ concentration in the postsynaptic cell initiates a chain of events at the synapse secondary to the activation of numerous $Ca^{2+}$ dependent enzymes. ④ This results in postsynaptic hyperexcitability as a consequence of phosphorylation and altered expression of membrane proteins, including an increase in EAA receptor number. ⑤ This may be augmented by release of retrograde transmitter(s) (possible candidates include NO and arachidonic acid) causing the presynaptic nerve terminal to enhance its release of EAA. Together pre- and postsynaptic events lead to enhanced transmission at the affected synapses. ⑥ These events are consolidated by changes in gene transcription and altered synaptic morphology, and while *induction* of LTP is prevented by NMDA antagonists, *established* LTP is unaffected by these agents. GLU=Glutamate; NMDA=*N*-methyl-D-aspartate; AMPA=α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate; mGluR=metabotropic glutamate receptor; PIP=phosphatidyl-inositol-4,5-bisphosphate; NO=nitric oxide; PLC=phospholipase C; $IP_3$=inositol-1,4,5-trisphosphate; $IP_3R$=$IP_3$ receptor; $PLA_2$=phospholipase $A_2$; G=GTP-binding protein; P=phosphorylation site; DAG= diacylglycerol; (a)=depolarization and action potential generation.

It is clear that volatile and i.v. anaesthetics inhibit EAA neurotransmission (table 1), and most,[13,101,124,125,126,179] but not all,[161] electrophysiological studies have suggested that hippocampal excitatory neurotransmission in particular is inhibited. Anaesthetic inhibition of EAA release and NMDA receptor function therefore has the potential to modify the induction (step 1) of LTP. Furthermore, there is evidence that $IP_3$-gated $Ca^{2+}$ stores are depleted by volatile anaesthetics[45] suggesting that the second phase of LTP-induction might also be sensitive to volatile anaesthetic inhibition. Is this a means by which anaesthetics suppress learning and memory?

Only two studies have specifically examined the effects of volatile anaesthetics on hippocampal LTP and these have produced conflicting results. MacIver, Tauck and Kendig[126] demonstrated that *in vitro*, both halothane and methoxyflurane at clinically relevant concentrations attenuated excitatory neurotransmission in the hippocampus, but while halothane markedly inhibited induction of LTP, methoxyflurane had no effect. In a separate study in which LTP was induced in the anaesthetized rat *in vivo*, it was reported that hippocampal excitatory neurotransmission and induction of LTP was unaffected by halothane, enflurane or isoflurane at clinically relevant concentrations.[161] The insensitivity of hippocampal neurotransmission to volatile anaesthetics in the latter study does not correlate with the inhibitory effects of volatile anaesthetics reported elsewhere, but it must be noted that control values for hippocampal neurotransmission in this study were measured in animals already anaesthetized with urethane, an agent which may itself affect excitatory neurotransmission in the hippocampus and induction of LTP.[174]

In conclusion, there is clear evidence that inhibition of EAA neurotransmission is a common property of general anaesthetics (although the presynaptic or postsynaptic locus of inhibition may vary with each agent), and direct, or indirect, modification of NMDA receptor function has been putatively proposed as the final common pathway of anaesthetic action.[66] However, although NMDA antagonists both contribute to the anaesthetic state and suppress memory, effects that are clearly associated with inhibition of hippocampal LTP *in vivo*, it remains uncertain if volatile and i.v. anaesthetic agents share this effect on LTP. Further studies are necessary to confirm whether the loss of awareness caused by general anaesthesia is a consequence of inhibition of LTP in the hippocampus or cerebral cortex.

## Excitatory amino acids and pain

Peripheral tissue injury creates a continuing noxious input to the spinal cord via Aδ and C-fibres which results in a progressive increase in the response of neurones within the spinal cord dorsal horn to further afferent input. This plasticity of spinal cord processing of nociceptive information plays a critical role in post-injury pain hypersensitivity[225] and chronic pain syndromes[30] and is termed central

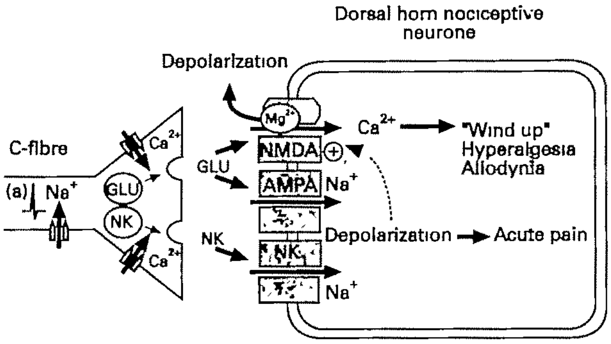

*Figure 4* Diagrammatic representation of the pharmacology of spinal pain transduction within the dorsal horn Acute pain is mediated by glutamate acting at AMPA/KA receptors and neurokinins acting at $NK_1$ receptors, the consequence of which is brief postsynaptic depolarization of dorsal horn neurones and activation of central pain pathways. More prolonged afferent input via Aδ and C-fibres causes NMDA receptor activation when AMPA receptor- and neurokinin receptor-mediated depolarization of the dorsal horn neurone is of sufficient magnitude and duration to remove the $Mg^{2+}$ block of the NMDA receptor LOC. NMDA receptor activation (with possible contribution from *m*Glu-receptor) leads to central sensitization and resultant hyperalgesia. GLU=Glutamate; NMDA=*N*-methyl-D-aspartate; NK=neurokinin; AMPA=α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate; (a)=depolarization and action potential generation.

sensitization. The pharmacology of central sensitization and spinal pain transduction has been a subject of many recent reviews[48 52 212 224 227] and it is clear that EAA play a key role (fig. 4). Aδ and C-fibre primary afferent nerve terminals within the substantia gelatinosa of the spinal cord release glutamate (and neurokinins) in response to noxious stimuli. Glutamate binds to both *i*Glu-receptor and *m*Glu-receptor subtypes which may be co-localized on the same postsynaptic cell. The acute response to injury at the synaptic level is mediated by glutamate acting at AMPA receptors and neurokinins acting at $NK_1$ receptors, the consequence of which is brief depolarization of dorsal horn neurones and activation of central pain pathways. More prolonged afferent input via Aδ and C-fibres causes NMDA receptor activation when AMPA receptor and neurokinin receptor mediated depolarization of the dorsal horn neurone is of sufficient magnitude and duration to remove the $Mg^{2+}$ block of the NMDA receptor channel. NMDA receptor activation (with a possible contribution from *m*Glu-receptor) leads to central sensitization and resultant hyperalgesia. Central sensitization may be consolidated by protein kinase C-mediated phosphorylation of the NMDA receptor which reduces the $Mg^{2+}$ gating characteristics of the channel[26]; indeed, inhibition of protein kinase C has been reported to prevent the development of hyperalgesia in a rat model of central sensitization.[230]

## ANAESTHETIC AND ANALGESIC EFFECTS ON SPINAL EAA MECHANISMS

Before reviewing the analgesic or "anti-hyperalgesic" potential of agents that block EAA receptors, it is of interest to examine how established anaesthetic and analgesic agents may interact with EAA neurotransmission in the spinal cord.

Sub-anaesthetic concentrations of some volatile anaesthetic agents may produce intense analgesia. Trichloroethylene and methoxyflurane were used previously for obstetric analgesia and there is good evidence that isoflurane may be similarly effective.[217] Such analgesia may be a consequence of direct effects on acute pain transduction at the level of the spinal cord where electrophysiological studies have shown isoflurane to inhibit nociceptive responses dependent on both NMDA receptor- and non-NMDA receptor-mediated EAA neurotransmission.[34 186 187] There is also some evidence[1 72 153] that modern volatile anaesthetic agents (halothane, enflurane, isoflurane and desflurane) can partially suppress spinal cord sensitization in a rat model in which subcutaneous formalin injection produces a biphasic behavioural response,[221] the second phase of which corresponds to dorsal horn NMDA receptor activation.[75] However, when formalin-induced sensitization in the spinal cord was measured by expression of the immediate early gene *c-fos* (a molecular marker of nociception[144]) halothane anaesthesia was without effect.[205] Therefore, the potential of volatile anaesthetics to influence pain in the postoperative period may be limited. Nitrous oxide has also been reported to inhibit central sensitization in a dose-dependent manner,[72 153] however nitrous oxide induces endorphin release[65] and its effects on central sensitization are partially reversed by naloxone. This does not suggest a direct effect on spinal EAA neurotransmission, but rather the activation of supraspinal opioid receptor mediated mechanisms which influence spinal sensitization.[70 74] Surprisingly, the effect of combined administration of nitrous oxide with either isoflurane[1] or halothane[72 153] was antagonistic and resulted in markedly less inhibition of central sensitization than did the administration of each volatile agent alone. The mechanism and site of this interaction is unclear, and further studies are warranted to assess the clinical significance of this finding.

The spinal analgesic actions of opioid agonists and $\alpha_2$-receptor agonists, at least in part, involve EAA neurotransmission. The demonstration that inhibition of the release of glutamate from dorsal horn nociceptive neurones is a consequence of both opioid[46 97] and $\alpha_2$-agonist[95] administration may explain their synergistic analgesic effects in animal models of pain.[141 158 159] Postsynaptically the NMDA receptor ion channel complex may be directly modulated in addition by $\mu$ opioid receptor agonists.[184] Furthermore, a complex interrelationship between NMDA receptor and $\mu$-opioid receptor mechanisms may control the development of spinal tolerance and dependence on opioids.[53]

## EAA ANTAGONISTS AS ANALGESICS

There is now a considerable literature encompassing the analgesic or antinociceptive effects of agents that inhibit EAA neurotransmission (for reviews see Dickenson,[48] Dray, Urban and Dickenson,[52] Sukiennik and Kream,[204] Urban, Thompson and Dray[212] and Yaksh and Malmbergh[227]). Many studies have focused on the NMDA receptor, where open-channel blockade,[31,61,228] competitive glutamate antagonism,[31,75] glycine site antagonism[31,49] or polyamine site manipulation[29] modify the response to painful stimuli in animal models of pain. Despite the diversity of pain models that have been used in these and other studies, most data suggest that NMDA receptor antagonism causes significant antinociception against persistent inflammatory or neuropathic models of pain but has little effect on brief nociceptive tests of acute pain. A clear demonstration of this effect is seen with the rat formalin model which may correspond to post-surgical pain; in this model which results in a brief acute pain behavioural response followed after a latent period by a longer inflammatory second phase associated with central sensitization, administration of NMDA receptor antagonists has no effect on the first phase but reduces or abolishes the delayed second phase of this test.[75,228] Similarly, in a study of human experimental pain, ketamine had no effect on a single noxious electrical stimulus, but had a marked analgesic effect on repeated stimuli associated with central sensitization.[6]

Given that the initial response to injury involves activation of AMPA receptors in the substantia gelatinosa, antagonism at this site has the potential to produce analgesia. Two groups have reported that the competitive AMPA antagonist NBQX has antinociceptive effects that differ qualitatively from those of NMDA receptor antagonism,[156,226] but a more recent study[31] failed to demonstrate any antinociceptive effect of AMPA antagonists in a variety of pain models. Irrespective of whether or not AMPA-antagonism can cause analgesia, it should be noted that Dickenson[47] considered that this pharmacological approach might be disadvantageous because it would not target a pathologically activated pain pathway but would inhibit a broad spectrum of afferent and efferent fast excitatory synaptic pathways throughout the CNS. Although NMDA receptor-mediated mechanisms are more specific to pain pathways it is unlikely to be their sole function in the spinal cord, for example spinal NMDA receptor-mediated pathways may also play a key role in the control of locomotion.[2] This could explain the motor dysfunction that has frequently accompanied administration of EAA antagonists and which has important implications regarding the interpretation of their effects in tests of nociception.[31] However, combined administration of competitive and non-competitive NMDA antagonists with agents acting at glycine and polyamine sites can produce highly effective antinociception in the formalin test without behavioural effects or motor dysfunction[32] and suggests that this problem may not be insurmountable.

## Excitatory amino acids and neurotoxicity

After traumatic or ischaemic damage to the CNS there is a pathological release of EAA from neurones and glia which plays a central role in mediating more extensive *excitotoxic* neuronal degeneration. In animal models, massive increases in extracellular levels of glutamate follow ischaemic[12] or traumatic insult to the brain[98] or to the spinal cord.[116] Similar increases in glutamate concentrations have been measured in cerebrospinal fluid in humans after head injury[11] and this increase appears to persist for several days after injury. These increased extracellular glutamate concentrations activate an excitotoxic cascade as a consequence of uncontrolled activation of both *i*Glu-receptors and *m*Glu-receptors. The molecular mechanism of this cascade has been reviewed recently[118] and can be summarized as follows (see fig. 5). $Ca^{2+}$ entry through both EAA-operated and voltage-operated $Ca^{2+}$ channels, together with $Ca^{2+}$ release from intracellular stores results in uncontrolled activation of neuronal protein kinases, phospholipases, proteases and nitric oxide synthase. The consequent proteolysis, lipid peroxidation and free radical formation results in degeneration of central neurones. Although EAA-mediated neuronal death can occur within minutes and a proportion of neurones die in the acute phase of injury, a large number of neurones instead suffer delayed death.[118] Much interest has therefore arisen from the potential to ameliorate excitotoxic neuronal damage by modification of EAA release, EAA receptor antagonism or inhibition of subsequent proteolysis and lipid peroxidation.[122]

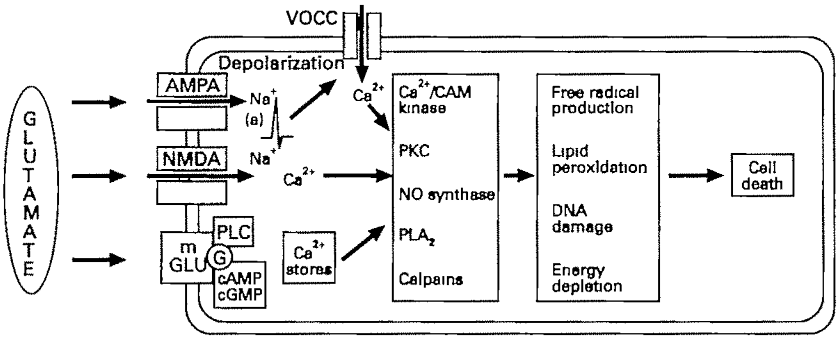

*Figure 5* Schematic representation of the central role of glutamate in excitotoxic neuronal injury (modified and redrawn from Lynch and Dawson[118]). ### STRATEGIES TO REDUCE EAA RELEASE

Of all the strategies to reduce EAA release, it is essential to first consider the beneficial effects of controlled hypothermia. It is well established that mild to moderate hypothermia results in significant cerebral protection against ischaemic brain injury[214]; this protective effect cannot wholly be explained by a global reduction in cerebral metabolic rate. However, it has recently been reported that mild to moderate hypothermia can markedly reduce the release of glutamate after experimental global cerebral ischaemia.[84] Given that the magnitude of this effect was much greater than the estimated reduction in global cerebral metabolic rate, the authors concluded that a reduction in glutamate release may contribute significantly to the neuroprotective effect of mild to moderate hypothermia.

As discussed previously, volatile anaesthetic agents, notably isoflurane[109] can strongly inhibit the depolarization-evoked release of EAA *in vitro* and it has been argued that this may result in protection from cerebral ischaemia. Recent evidence demonstrates that isoflurane can effectively inhibit the ischaemia-induced release of glutamate to an extent comparable with that of hypothermia[60 147 160] and may also reduce ischaemia-induced NMDA receptor activation *in vitro*,[16] however, in animal models of ischaemic neuronal injury, isoflurane anaesthesia does not appear to reduce injury in comparison with nitrous oxide anaesthesia[215] and its neuroprotective potential *in vivo* remains the subject of debate.

Several novel anticonvulsant agents share a common mechanism of action in that they reduce EAA release from central neurones, probably as a consequence of an inhibitory effect at presynaptic $Na^+$ channels.[211] This class of agents are neuroprotective in animal models of focal or global cerebral ischaemia: thus riluzole,[167] felbamate,[216] lamotrigine and its congeners[196 222] all reduce infarct size or neuronal loss after ischaemic insult and may improve neurological outcome and survival. They are most effective when administered before ischaemia, but importantly, a window of opportunity appears to exist in the immediate post-ischaemic period when their administration is also protective.

### EAA ANTAGONISTS AS NEUROPROTECTIVE AGENTS

Postsynaptic neuronal depolarization, both as a direct consequence of ischaemia and as a result of *i*Glu-receptor activation, removes the $Mg^{2+}$ block of the NMDA receptor thereby allowing uncontrolled $Ca^{2+}$ entry via the NMDA receptor LOC. In consequence NMDA receptor antagonists have attracted much interest as potential cerebral protective agents.[113]

Competitive antagonists at the NMDA receptor such as d-CPP-ene and CGS 19755 are clearly neuroprotective when administered pre-emptively or immediately after injury in models of global and focal ischaemia.[135] However, their efficacy when administered after injury/ischaemia may be limited by the relatively slow penetration into the CNS after parenteral administration, consequently there may therefore be only a narrow window of opportunity for their administration. Open-channel NMDA antagonists such as dizolcipine have the theoretical advantage over competitive EAA antagonists in that antagonism should not be overcome by the pathologically high glutamate concentrations associated with cerebral ischaemia. Dizolcipine clearly provides protection in animal models of cerebral ischaemia[89] and traumatic injury to the brain or spinal cord.[63] Again, cerebral protection is evident whether administered before or after injury, but although agents such as dizolcipine penetrate readily into the CNS after systemic administration, it is unclear if they are more effective when administered after injury than are competitive antagonists. A variety of other open-channel NMDA antagonists have been shown to have experimental neuroprotective properties[113] and, significantly, these include agents which have been used in humans such as the dissociative anaesthetic ketamine[117] and the antitussive agent dextromethorphan.[27 62]

The multiple modulatory sites of the NMDA receptor provide other potential pharmacological targets for cerebral protection. For example, the neuroprotective properties of felbamate may result from glycine site antagonism in addition to its previously described effects on glutamate release.[211 216] Nitroso compounds such as nitroprusside or glyceryl trinitrate which interact with the redox modulatory site and prevent EAA-induced neuronal death *in vitro*,[110 114] are another intriguing class of agents with potential neuroprotective properties.[73] The degree of physiological blockade of the NMDA receptor channel by $Mg^{2+}$ ions may also be an important determinant of neuronal injury, particularly given that tissue $Mg^{2+}$ concentrations have been reported to decline rapidly after both major surgery[185 207] and CNS injury.[111] Magnesium administration has been reported to be protective against CNS ischaemia,[71 195 213] and enhanced blockade of the NMDA receptor channel may at least in part underlie this action.

## Clinical implications

The ubiquity of EAA neurones throughout the CNS emphasizes the importance of EAA-mediated neurotransmission in anaesthesia, analgesia and neurological intensive care. Equally, the importance of EAA neurotransmission in cognition, memory, sensation and motor function certainly contributes to the broad spectrum of neuropsychological side effects that have limited the clinical use of dissociative anaesthetic agents such as ketamine. Nevertheless, we already influence this system with the use of volatile (and to a lesser extent i.v.) anaesthetic agents without all of these adverse effects. Furthermore, there is evidence that indicates that it may be the high affinity of established dissociative anaesthetic agents (including ketamine) for the NMDA receptor, and their slow dissociation from the open-channel binding site, that results in their adverse neuropsychological profile.[180] Drugs with more rapid dissociation kinetics from the open channel, or those interacting with other binding sites on the NMDA receptor, may have a more attractive side effect profile, and these together with their targeting at spinal (as opposed to higher) centres provides the potential for a broader clinical use of these agents. Much interest has centred on the role of EAA neurotransmission in the fields of pain[48 52 212 227] and cerebral protection[89 113 135 180] although less emphasis has been placed on its potential role in anaesthesia.

There is no doubt that inhibition of EAA neurotransmission in the CNS, by antagonism of a variety of receptor sites[39 40 41 120 121 189] and to a lesser extent by inhibition of glutamate release,[130] can promote or induce anaesthesia but the adverse behavioural effects of high doses of many of these agents make it unlikely that they could be widely exploited for clinical anaesthesia, particularly where rapid recovery is required. However, the ability of this group of drugs to reduce the MAC of other anaesthetic agents suggests that they could have a useful role, particularly in high-risk patients. The added advantages of intense analgesia and cerebral protection suggest that inhibition of EAA neurotransmission may contribute to optimally balanced anaesthesia with special relevance to trauma, cardiac and neurosurgery. Furthermore, given the ability of NMDA antagonists to inhibit LTP and induce anterograde amnesia, these agents may prove useful in this high-risk group to reduce the risk of intraoperative awareness.

The importance of the NMDA receptor in the induction and maintenance of central sensitization and the contribution of this process to both acute surgical pain and perhaps more importantly, chronic pain syndromes strongly suggests that agents affecting spinal EAA neurotransmission may be useful analgesic agents in areas where currently available agents are of only limited efficacy. As discussed above, this could involve the systemic administration of such agents as anaesthetic adjuncts, and there is, for example, evidence that systemic peroperative administration of ketamine may reduce postoperative wound hyperalgesia[209] and analgesic requirements[183 209] without psychotomimetic side effects. There is also recent evidence that similar benefit may be achieved with the peroperative administration of magnesium sulphate,[207] an effect that at least in part may be a consequence of NMDA ionophore blockade.

In the chronic pain setting, several reports indicate that ketamine can provide analgesia and relief of hyperaesthesia/allodynia in neuropathic pain resistant to conventional therapy with tricyclic antidepressant, anticonvulsant and membrane stabilizing agents.[10 59 151 200] Similarly, subcutaneous or i.v. infusion of ketamine may be highly efficacious in opioid-resistant cancer pain.[136] Unfortunately, in several cases, dosage has been limited or treatment terminated by psychotomimetic effects, and certainly for outpatient treatment of chronic pain, an agent lacking psychotomimetic effects and suitable for oral administration is ideally required. The antitussive dextromethorphan is the only other agent in clinical use with NMDA antagonist activity[28] and it has a good safety record, but a study of oral administration of this agent failed to show any benefit in a group of patients with neuropathic pain resistant to conventional therapies.[127] However, there is an encouraging recent report of oral administration of ketamine providing pain relief without significant side effects in opioid-resistant neuropathic pain.[23]

In an attempt to limit supraspinally mediated adverse effects, considerable interest has focused on intrathecal or extradural administration of NMDA receptor antagonists, thereby targeting EAA synapses in the substantia gelatinosa of the spinal cord. While experience in human subjects is limited, animal studies convincingly demonstrate the effectiveness of spinally administered NMDA receptor antagonists in a variety of pain models corresponding to both post-surgical and chronic pain states. Although many of the studies of NMDA receptor open-channel blockers such as ketamine and dizolcipine (MK801) have shown significant motor and behavioural effects even after spinal administration, co-administration of low doses of open-channel blockers with agents acting at other regulatory sites on the NMDA receptor may circumvent behavioural and motor problems[32] rendering them more suitable for clinical use. Concern has also been expressed regarding the neurotoxicity of ketamine and dizolcipine.[129 154 155] However, low concentrations of preservative-free ketamine are not neurotoxic[21] and have been used in humans by both intrathecal[18] and extradural[85 99 145 173] routes. Competitive antagonists may have fewer adverse effects and there is evidence that the potent NMDA antagonist CPP is effective in several pain models at doses that do not affect motor function or behaviour.[104] This finding, together with its apparent lack of neurotoxicity[105] or effect on spinal cord blood flow,[103] indicates that CPP may be a prototypical agent for clinical spinal administration in human.

Pathological release of glutamate clearly plays a key role in ischaemic excitotoxic damage to the CNS. It is possible to modify both the release of glutamate and its receptor-mediated effects at multiple sites and a combination of agents acting both pre- and postsynaptically, perhaps in conjunction with mild to moderate hypothermia, may be necessary to minimize neuronal damage. Concern has been expressed over the behavioural and neuropsychological effects of glutamate antagonists—particularly those acting at the NMDA open-channel site—at the dosage required for cerebral protection.[113] However, both memantine (an anti-Parkinsonian drug which blocks the NMDA receptor open-channel site with low affinity and rapid kinetics of dissociation) and felbamate (a glycine site NMDA receptor antagonist and an inhibitor of glutamate release) have been shown to be effective in animal models of CNS ischaemia at concentrations that are tolerated clinically in humans.[25 216] They may therefore be prototypical agents for perioperative use in neurosurgical and perhaps cardiac anaesthesia if rapid recovery is required. The multiple facets of EAA-mediated excitotoxicity provide many intriguing therapeutic possibilities in this area and in addition to evaluating new agents it may be necessary to reappraise the use of established techniques, including volatile anaesthetics, magnesium administration and the use of nitroso compounds such as glyceryl trinitrate.

The clinical pharmacology of EAA neurotransmission is still in its infancy; few of the agents that specifically influence EAA release or interact with the growing family of glutamate receptors have as yet progressed beyond preliminary clinical studies or isolated case reports. Nevertheless, an understanding of this rapidly expanding field of pharmacology is of paramount importance in order that we may optimize our management of high-risk patients and acute or chronic pain.

SHORT COMMUNICATIONS

# Continuous extradural infusion of ropivacaine 2 mg $ml^{-1}$ for pain relief during labour

D. BENHAMOU, J. HAMZA, J.-J. ELEDJAM, P. DAILLAND, M. PALOT, J. SEEBACHER,
D. MILON AND K. HEEROMA

## Summary

We have assessed the dose–response relationship of a solution of ropivacaine 2 mg $ml^{-1}$, given as a continuous extradural infusion to women in labour. A total of 133 parturients were allocated randomly to one of four groups to receive a fixed rate ropivacaine infusion of 4, 6, 8 or 10 ml $h^{-1}$ with additional bolus doses as necessary. Contraction pain, quality of analgesia, sensory block, motor block and neonatal Apgar scores were assessed. There were no significant differences between groups in terms of analgesia or motor block, although significantly more bolus doses were required by the group receiving 4 ml $h^{-1}$ ($P<0.05$ compared with the other groups), and a significantly higher total dose of ropivacaine was administered to the 10-ml $h^{-1}$ group compared with the 6-ml $h^{-1}$ group ($P=0.044$). There were no significant differences between groups in terms of obstetric or neonatal outcome. We conclude that ropivacaine 2 mg $ml^{-1}$ was effective and well tolerated when given as a continuous extradural infusion at 6–8 ml $h^{-1}$ and may be used as the sole analgesic during labour. (*Br. J. Anaesth.* 1997; **78**: 748–750).

**Key words**
Anaesthesia, obstetric. Anaesthetics local, ropivacaine. Analgesia, obstetric. Analgesic techniques, extradural.

Ropivacaine is a long-acting amide local anaesthetic and is the first enantiomerically pure anaesthetic of its type to be developed. It has been shown to have lower central nervous system and cardiovascular toxicity, and to produce slightly less motor block than equivalent doses of bupivacaine in surgical patients.[1] Several studies have compared ropivacaine 2.5 mg $ml^{-1}$ with bupivacaine 2.5 mg $ml^{-1}$ for analgesia in labour.[2–4] Although most factors were found to be affected similarly by each drug, ropivacaine was associated with a significantly lower incidence of instrumental delivery,[3] and higher neurological adaptive capacity scores (NACS) of the neonate, 2 and 24 h after delivery,[3 4] which in one case were significantly improved.[3] Furthermore, a volunteer study[5] suggested that ropivacaine 2 mg $ml^{-1}$ infused at rates of 10, 20 and 30 mg $h^{-1}$, may have a more favourable sensory:motor block ratio than bupivacaine 2.5 mg $ml^{-1}$, given as 25 ml $h^{-1}$. As this lower concentration of ropivacaine has not yet been evaluated in labour, we have investigated the dose–response relationship of different volumes of ropivacaine 2 mg $ml^{-1}$, administered by continuous extradural infusion, in terms of analgesia and motor block during labour, and obstetrical and neonatal outcomes, in a seven-centre open study.

## Methods and results

We studied 134 parturients in whom extradural analgesia was planned, and who were at least 18 yr of age, of less than 110 kg body weight, and pregnant with a singleton fetus (in the vertex position); they were allocated randomly to one of four groups to receive ropivacaine 2 mg $ml^{-1}$ at fixed extradural infusion rates of 4, 6, 8 or 10 ml $h^{-1}$ (8, 12, 16 or 20 mg $h^{-1}$). The investigation, which was approved by the Ethics Committee of the co-ordinating centre, was explained fully to the patients (according to the Helsinki declaration) and written consent was obtained.

Exclusion criteria included: a history of allergy or sensitivity to amide local anaesthetics; administration of analgesics before the extradural; maternal medical conditions such as neurological disease, pre-eclampsia, drug abuse or psychiatric illness; and known fetal abnormalities.

The extradural procedure was started during labour. After local infiltration, a 16–18 gauge Tuohy needle was inserted in one of the L1–4 vertebral

interspaces and the extradural catheter sited after intravascular or intrathecal placement had been excluded. An initial dose of ropivacaine 10 ml was delivered by fractional injection. The ropivacaine infusion was started within 15 min of the initial dose and was continued until delivery. Additional 5-ml bolus doses were allowed at the discretion of the investigator during the infusion period, providing the total dose did not exceed 450 mg, or 175 mg in any 3-h period.

Administration of oxytocin was allowed at any time during the procedure and patients experiencing hypotension or bradycardia received ephedrine or volume loading, or both. If concurrent analgesics other than nitrous oxide were required before delivery, the patient was withdrawn from the study.

Onset of pain relief was assessed at each contraction using a four-point verbal scale. Contraction pain was assessed using a visual analogue scale (VAS), graded from 0 mm (no pain) to 100 mm (worst imaginable pain). Assessments were made for two consecutive contractions 5–10 min before commencing the extradural procedure, after the initial dosing, and thereafter at the first contraction after successive 30-min intervals. Spread of sensory block was assessed bilaterally every hour by pinprick. Overall quality of pain relief throughout labour was evaluated by the parturient immediately after delivery. Motor block was assessed bilaterally every hour using the modified Bromage scale, and other assessments made are listed in table 1. All adverse events for mother, fetus and neonate were recorded during labour, and at regular post-partum follow-ups until 2–3 weeks after birth. No attempt was made to standardize obstetric management between centres as the primary goal of this study was to evaluate analgesia.

Data were analysed using Wilcoxon rank sum tests or chi-square tests, stratified for centre. *P* values were adjusted for multiple comparisons using the Bonferroni–Holm method and those values <0.05 were considered statistically significant.

The four groups were similar in patient characteristics and 54 women were multiparae. Of the 134 parturients, data from 133 who received ropivacaine were valid for analyses of efficacy and safety and are summarized in table 1.

Duration of treatment, was slightly, but not significantly, longer in the 10-ml h$^{-1}$ group (median 4.63 h compared with 3.55–4.11 h). Total dose of ropivacaine administered, however, was significantly higher in the 10-ml h$^{-1}$ group (median 127.6 mg) than in the 6-ml h$^{-1}$ group (median 84.6 mg). Furthermore, the number of bolus doses administered per hour was significantly higher in the 4-ml h$^{-1}$ group than in the other groups ($P$=0.025 (4 ml h$^{-1}$ *vs* 6 ml h$^{-1}$); $P$=0.001 (4 ml h$^{-1}$ *vs* 8 ml h$^{-1}$); $P$=0.0002 (4 ml h$^{-1}$ *vs* 10 ml h$^{-1}$)). There were no significant differences between groups in any of the characteristics of analgesia and motor block scores immediately before transition to stage 2 of labour. The incidence of spontaneous head delivery was similar between groups (63–76%). Median Apgar scores of all neonates at 1 and 5 min after delivery were 9 and 10, respectively, with four newborns having scores of <7, 1 min after delivery. At 5 min after delivery, only two newborns had scores of <10 and both children registered scores of 9.

The incidence of adverse events was similar between groups. The most frequent adverse event in the mothers, fetuses and neonates was mild to moderate hypotension (19 of 133), deceleration (25 of 133) and temporary jaundice (36 of133), respectively.

## Comment

Ropivacaine 2 mg $ml^{-1}$ was effective as an extradural analgesic. The percentage of patients rating the quality of pain relief as "good" or "excellent" ranged from 74% (4-ml $h^{-1}$ group) to 88% (6- and 10-ml $h^{-1}$ groups). In most patients, VAS scores for subjective pain remained well below the 30-mm score regarded widely as the threshold level at which pain requires treatment. In the group receiving ropivacaine 4 ml $h^{-1}$, median VAS score, however, increased to 30 mm in the last third of labour and significantly more additional bolus doses were required by patients in this group to maintain adequate analgesia throughout labour. The 4-, 6- and 8-ml $h^{-1}$ groups received similar total doses of ropivacaine (median 82.8–86.4 mg) and the 10-ml $h^{-1}$ group received a significantly higher total dose (median 127.6 mg) than the 6-ml $h^{-1}$ group ($P$=0.044). A higher incidence of motor block in the 10-ml $h^{-1}$ group, although potentially troublesome, was not statistically significant.

These findings suggest an optimum infusion rate for ropivacaine 2 mg $ml^{-1}$, of 6–8 ml $h^{-1}$, because at 4 ml $h^{-1}$ more bolus doses per hour were required and there was a trend towards inferior analgesia, while at 10 ml $h^{-1}$ a higher total dose was given and increased motor block detected.

Several studies investigating the use of ropivacaine 2.5 mg $ml^{-1}$ for analgesia in labour have demonstrated that ropivacaine offers advantages over bupivacaine 2.5 mg $ml^{-1}$ in terms of both mode of delivery and neonatal outcome.[2–4] In a prospective meta-analysis[3] in which mean extradural doses of ropivacaine and bupivacaine were 103 (range 12.5–278) mg and 100 (25–337.5) mg, respectively, the number of instrumental deliveries (forceps and vacuum) was significantly less frequent with ropivacaine than with bupivacaine: 27% (54 of 199) *vs* 40% (75 of 188) ($P<0.05$). In addition, the ropivacaine group had significantly better NACS scores 24 h after delivery than the bupivacaine group: 2.8% (four of 144) with a score of less than 35 *vs* 7.6% (11 of 144) ($P<0.05$). There were no differences between the groups in the incidence of adverse events for mothers, fetuses or neonates. It is interesting to note that the dose of ropivacaine administered and the number of instrumental deliveries in our study were both slightly lower than those reported in the meta-analysis.

We conclude that ropivacaine, at a concentration of 2 mg $ml^{-1}$, produced adequate and well-tolerated analgesia for pain in labour when administered as a continuous extradural infusion with supplementary bolus doses. Infusion rates of 6–8 ml $h^{-1}$ are recommended to minimize additional bolus injections and the total dose given.

# Processed electroencephalogram during combined extradural and general anaesthesia

S. Kiyama and K. Tsuzaki

---

## Summary

The processed electroencephalogram (pEEG) was monitored in eight patients undergoing gynaecological laparotomy under combined extradural and nitrous oxide–isoflurane anaesthesia. Pre-incisional mean spectral edge frequency 95 percentile (SEF95) and median frequency (MF) were 11.67 (SD 1.63) Hz and 3.74 (0.24) Hz, respectively. After skin incision, both SEF95 and MF decreased to 6.61 (2.04) Hz and 2.72 (0.32) Hz, respectively ($P<0.001$). An increase in mean arterial pressure after incision suggested inadequate depth of anaesthesia. After introduction of extradural analgesia, these variables returned to pre-incisional values (SEF95 11.65 (1.73); MF 4.02 (0.41)). Reduction of end-tidal isoflurane from 1.0% to 0.5% after extradural analgesia did not cause significant pEEG changes. pEEG may assist anaesthetists to recognize adequacy of combined general–extradural anaesthesia. (*Br. J. Anaesth.* 1997; **78**: 751–753).

---

Extradural analgesia has often been combined with light general anaesthesia in major surgery. The sympathetic block produced by extradural analgesia with the negative inotropic action of general anaesthetics may cause further cardiovascular depression. Therefore, it is advisable to avoid a high dose of general anaesthetics in order to prevent haemodynamic derangements.

However, even under adequate extradural analgesia, it is not known if patients remain unconscious during light general anaesthesia. Despite anaesthetists' concerns about intraoperative awareness, particularly in paralysed patients, there have been no studies of intraoperative EEG under combined general–extradural anaesthesia.

## Methods and results

After obtaining Institutional Review Board approval and informed consent, we studied eight ASA I patients, aged 33–66 yr, weighing 45–58 kg, undergoing abdominal hysterectomy.

After oral premedication with ranitidine 150 mg, 2 h before anaesthesia, an extradural catheter was sited at L2–3 or L3–4. Lignocaine 1% (2 ml) was used for local infiltration anaesthesia. Extradural test doses consisted of 3 ml of 1% lignocaine with adrenaline 1:200 000. No further local anaesthetic was given before induction of anaesthesia with thiopentone 5 mg $kg^{-1}$ i.v. Vecuronium was administered to facilitate tracheal intubation and surgical exposure. Positive pressure ventilation was adjusted to maintain normocapnia (end-tidal carbon dioxide partial pressure of 4.5–5.0 kPa), measured with an anaesthetic gas monitor (Capnomac Ultima, Datex, Helsinki, Finland). Non-invasive arterial pressure, electrocardiogram, oxygen saturation, urine output and rectal temperature were monitored.

After induction, the lungs were ventilated with 1.0% end-tidal isoflurane and 65% nitrous oxide in oxygen. We waited 15 min after intubation before the start of surgery (phase 1). During the first 15 min after incision, anaesthesia was continued with the same concentration of inhalation agents as above (phase 2). Then 1.5% plain lignocaine 20 ml were administered extradurally in 5-ml incremental doses in 6 min and inhalation anaesthesia was maintained as above for another 15 min (phase 3). The end-tidal concentration of isoflurane was then reduced to 0.5% with 65% nitrous oxide in oxygen and 15 min elapsed until the end of the study (phase 4).

A Dräger pEEG monitor (Dräger AG, Lübeck, Germany) was used to monitor continuously pEEG. Four disposable electrodes were placed over the frontal and mastoid areas bilaterally. A reference electrode was placed in the frontal midline. Impedance of the electrodes was measured every 3 min and maintained below 5 kΩ throughout the study. Conventional frequency bands were used to describe power spectrum variables. Epoch length of EEG acquisition was 2 s. pEEG data were recorded onto a PC-compatible computer showing the trend of spectral edge frequency (SEF) and raw EEG waveform, and on postoperative replay the trace of raw EEG was inspected to ensure that artefacts caused by diathermy were excluded in the off-line analysis.

For statistical analysis, the pEEG data were averaged from 10 consecutive epochs in the last 5 min of each study phase. Mean arterial pressure and heart rate were expressed as percentage of baseline values.

One-way repeated measures ANOVA followed by Tukey's multiple comparison was performed using StatView 4.0 (Abacus Concepts, Inc., Berkeley, CA, USA).

There were no differences between the four phases for end-tidal carbon dioxide concentration, oxygen saturation or rectal temperature.

After surgical incision, SEF95 and MF decreased in all eight patients (table 1). After extradural analgesia, these pEEG variables returned to pre-incisional values. There was no significant change in pEEG variables after reduction of end-tidal isoflurane concentration from 1.0% to 0.5%.

The only significant haemodynamic change was an increase in mean arterial pressure after incision.

## Comment

pEEG shifted towards slower waves after incision in all eight patients. Intraoperative EEG slowing has been considered to reflect increased depth of anaesthesia. However, a significant increase in arterial pressure after incision suggests that anaesthesia at that time was not adequate enough to suppress sympathetic responses.

EEG slowing associated with clinical arousal phenomena caused by surgical stimulation is termed "paradoxical arousal".[1] Controversy exists as to the characteristic EEG changes induced by surgery. Sensory stimulation may induce a shift of the dominant EEG frequency towards faster waves,[2 3] which is similar to what occurs during emergence from anaesthesia.[4] On the other hand, Bimar and Bellville described that EEG patterns, as either increases in high-frequency or low-frequency activity, may represent intraoperative arousal.[5] EEG responses with increases in low-frequency activity were most prominent at frontal areas.[6] In our study, electrodes were placed in the bilateral fronto-mastoid areas, thus reflecting mostly electrical activity in the frontal cortex. This may be the reason why "paradoxical arousal" patterns were identified clearly.

All pEEG variables returned to pre-incisional values after extradural analgesia. It may be criticized that it is impossible to assess the efficacy of extradural analgesia in anaesthetized patients. However, with the general–extradural technique, anaesthetists rely on haemodynamic changes to decide on the timing of extradural dosing and assess its effectiveness. Mean arterial pressure decreased significantly after administration of extradural lignocaine. Mean blood loss at that point was less than 50 ml. Therefore, it is likely that the decrease in arterial pressure in phase 3 resulted from effective extradural analgesia. Our results suggest that the "paradoxical arousal" phenomenon disappeared after achievement of analgesia.

Although there was a slight increase in SEF95 after reduction of end-tidal isoflurane from 1.0 to 0.5%, the difference was not statistically significant. Drummond and colleagues identified a threshold value for SEF of 13.6 Hz which provided separation from surgical anaesthesia to pre-arousal state during emergence from isoflurane–nitrous oxide anaesthesia.[4] Mean SEF95 in phase 4 was less than this threshold value and none of our patients had intraoperative recall. In view of the duration of effect of 1.5% lignocaine, it is unlikely that extradural analgesia was wearing off in phases 3 and 4. We assume that when afferent noxious stimuli are interrupted by extradural analgesia, a modest reduction in dose of inhalation agent may not cause significant changes in pEEG variables, although the possibility of low statistical power resulting from small numbers of subjects cannot be excluded.

Cardiovascular variables have been the only variables available to assess the efficacy of extradural analgesia in anaesthetized, paralysed patients. There was a significant change in mean arterial pressure after incision and also after extradural analgesia. It may thus be argued that in these healthy patients, pEEG did not provide any additional information that was not readily apparent from haemodynamic observations. However, intraoperative haemodynamic state can also be affected by other factors apart from depth of anaesthesia, such as volume status and concomitant cardiac medications. Consequently, it may be of clinical significance that pEEG variables showed significant changes after incision and extradural analgesia.

# "Best" PEEP during one-lung ventilation

S. INOMATA, T. NISHIKAWA, S. SAITO AND S. KIHARA

## Summary

Eight patients were studied under general anaesthesia for elective pulmonary lobectomy to see if intrinsic positive end-expired pressure (PEEPi) would appear or increase in the dependent lung during one-lung ventilation (OLV) or if application of external PEEP equal to individually measured PEEPi would produce better arterial oxygenation, haemodynamic state and oxygen delivery than either zero PEEP (ZEEP) or an external PEEP 5 cm $H_2O$ greater than PEEPi. Patients were non-obese, without obstructive airways disease, aged 53–76 yr and ASA <III. They received standardized anaesthesia with fentanyl, 50% nitrous oxide in oxygen and isoflurane; monitoring included radial and fibreoptic pulmonary arterial catheters and intermittent positive pressure ventilation with a tidal volume of 8 ml $kg^{-1}$, 16 bpm, and an I:E ratio of 1:2. PEEPi was measured during two-lung ventilation (TLV) and OLV, using rapid airway occlusion at end-expiration. There was no PEEPi during TLV, but 2–6 mm Hg of PEEPi appeared during OLV. Applying external PEEP equal to individually measured PEEPi reduced venous admixture and increased $Pa_{O_2}$ without a decrease in cardiac index (thus increasing oxygen delivery) compared with ZEEP, but the improvement in pulmonary gas exchange was lost and an additional penalty of reduced cardiac output was imposed when external PEEP was increased to 5 mm Hg above PEEPi. (*Br. J. Anaesth.* 1997; **78**: 754–756).

Surgery, thoracic. Lung, shunting. Ventilation, mechanical. Ventilation, positive end-expiratory pressure. Ventilation, one-lung.

Hypoxaemia during one-lung ventilation (OLV) for thoracotomy in patients in the lateral position remains a clinical problem. In the majority of cases, hypoxaemia can be prevented by the use of a high inspired oxygen concentration ($FI_{O_2}$), by increasing tidal volume or by application of positive end-expiratory pressure (PEEP) to the non-dependent lung. In some clinical situations, however, management of OLV using these techniques is inappropriate or ineffective for maintaining adequate oxygenation.

Accordingly, the use of PEEP to the ventilated, dependent lung[1,2] is used to minimize ($PA_{O_2}-Pa_{O_2}$) and improve oxygenation during OLV in the lateral position. However, use of excessive PEEP to the dependent lung often impairs oxygenation by diverting blood to the non-dependent lung. Contradictory results have been reported in previous studies on the use of PEEP to the dependent lung during OLV.[1,2] Hence, it is important to devise anaesthetic techniques which provide optimal arterial oxygenation during OLV.

Under most circumstances, airway resistance increases because of a decrease in the compliance of the dependent lung during OLV with the patient in the lateral position, while intrinsic PEEP (PEEPi) is most likely to exist when airway resistance is increased.[3,4] In this regard, PEEPi is likely to appear in the dependent lung during OLV in the patient in the lateral decubitus position, primarily because of high airway resistance from a relatively small tracheal tube at the minute volumes and ventilatory frequencies used during OLV. Moreover, PEEPi, which is used in several types of mechanical ventilation, is suggested to improve oxygenation, and we hypothesized that each patient has an individual optimal PEEP which could be close to measured PEEPi.

Based on these considerations, this study was conducted in patients with normal pulmonary function to exclude any effects of obstructive airways disease on production of PEEPi, to clarify if PEEPi would appear in the dependent lung during OLV in patients in the lateral position, and to determine the PEEP value that best enhanced both oxygenation and haemodynamic state when zero PEEP (ZEEP), the equivalent PEEPi value or PEEPi plus 5 mm Hg was randomly applied externally to the dependent lung during OLV.

## Methods and results

We studied eight adult patients, ASA I or II, aged 53–76 yr, undergoing mechanical ventilation via a double lumen endobronchial tube for elective lung lobectomy. The study was approved by our Clinical Investigation Committee, and informed consent was obtained from each patient. No patient was obese and none had a history of obstructive airways disease.

After arrival in the operating room, an i.v. cannula

Correspondence to S. I.

and a radial arterial catheter were placed for infusion of lactated Ringer's solution 5 ml $kg^{-1}$ $h^{-1}$ and for continuous monitoring of arterial pressure and arterial blood sampling, respectively. General anaesthesia was induced with thiamylal 5 mg $kg^{-1}$ i.v. and the left main bronchus was intubated orally after vecuronium 0.2 mg $kg^{-1}$ i.v. Anaesthesia was maintained with 1% inspired isoflurane and nitrous oxide in oxygen ($FI_{O_2}$=0.5), delivered via a left-sided 37-Fr double lumen tube (Broncho-cath; Mallinckrodt Laboratories Co., Ltd., Athlone, Ireland), in addition to a total i.v. dose of fentanyl 5 μg $kg^{-1}$. The lungs were ventilated mechanically throughout the study with a tidal volume of 8 ml $kg^{-1}$, ventilatory frequency of 16 bpm and an inspiratory to expiratory ratio of 1:2. A 7.5-Fr pulmonary artery catheter (oximetry/right ventricular ejection fraction (RVEF) thermodilution catheter, model 93A-750H-7.5F, Baxter, Irvine, CA, USA) was inserted and advanced into the pulmonary artery. Haemodynamic and oxygenation data were obtained from the radial artery catheter and the pulmonary artery catheter.

## MEASUREMENT OF PEEPI VALUE

Airway pressure, including PEEPi, was measured via a side hole proximal to the endobronchial tube using a calibrated pressure transducer. We used the rapid airway occlusion technique to detect and measure PEEPi at end-tidal expiration during TLV with the patient in the supine and lateral positions, and during OLV with the patient in the supine and lateral positions.

After a stabilization period of 20 min, measurements were made during conventional TLV in the supine position. Next, after patients were placed in the lateral decubitus position, the same measurements were performed during TLV. After right or left thoracotomy, measurements were repeated during OLV with external application of ZEEP, PEEP equivalent to PEEPi in each patient, and PEEPi plus 5 mm Hg to the dependent lung. All measurements were carried out after patients were judged to have reached a steady state by confirming stability of $Sp_{O_2}$, arterial pressure, heart rate and airway pressure for at least 10 min. Measurements during OLV with external application of ZEEP, PEEPi and PEEPi plus 5 mm Hg to the dependent lung were performed randomly, and were completed within 60 min before manipulation of the pulmonary vessels. CI, $\dot{Q}s/\dot{Q}t$, $Do_2I$ and pulmonary vascular resistance index (PVRI) were calculated using standard formulae.

## STATISTICAL ANALYSIS

All values are expressed as mean (SD). Statistical comparisons were performed using ANOVA for repeated measures with Fisher's least significant difference test for *post hoc* analysis. $P<0.05$ was considered the minimum level of statistical significance.

We found that a PEEPi of 4 (2) mm Hg (range 2–6 mm Hg) appeared in the dependent lung during OLV in the lateral position. In contrast, PEEPi did not appear during TLV in the supine and lateral decubitus positions. In addition, PEEPi did not appear during OLV in the supine position. PEEPi of 5–6 mm Hg was noted in patient Nos 3, 5, 6 and 7 in whom peak airway pressure increased by more than 7 mm Hg during OLV compared with that during TLV. Haemoglobin concentration remained unchanged throughout the study.

When ZEEP was applied to the dependent lung during OLV in the lateral position, $Pa_{O_2}$, $\dot{Q}s/\dot{Q}t$, CI, $Do_2I$, RVEF and PVRI were 12.3 (3.3) kPa, 30 (11) %, 3.14 (0.74) litre $min^{-1}$ $m^{-2}$, 500 (153) ml $min^{-1}$ $m^{-2}$, 33 (5) % and 208 (64) dyn s $cm^{-5}$ $m^{-2}$, respectively (fig. 1). External application of PEEPi

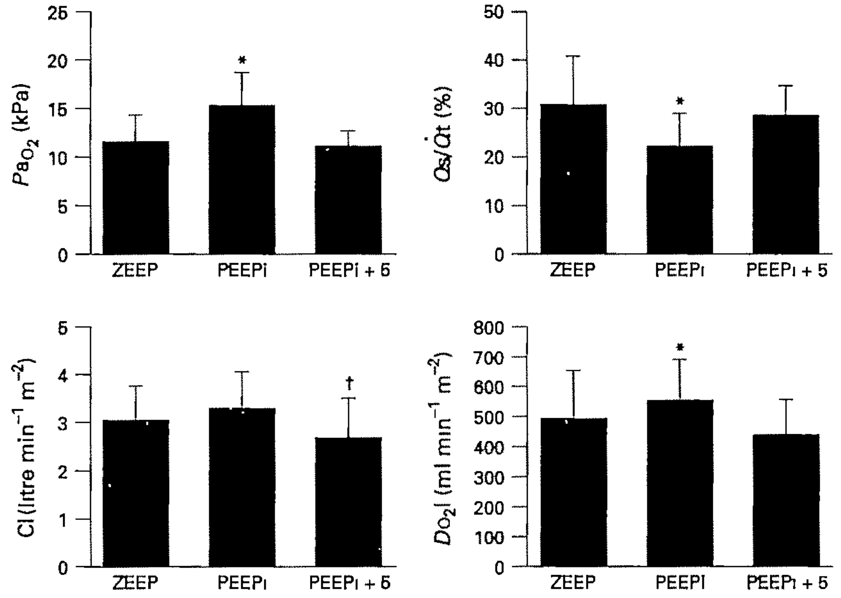

*Figure 1* Changes in arterial partial pressure of oxygen ($Pa_{O_2}$), physiological shunt ($\dot{Q}s/\dot{Q}t$), cardiac index (CI) and oxygen delivery index ($Do_2I$) during one-lung ventilation with external application of zero end-expiratory pressure (ZEEP), intrinsic PEEP (PEEPi) and PEEPi plus 5 mm Hg (PEEPi +5) to the dependent lung, while patients were placed in the lateral decubitus position $^*P<0.05$ compared with other two periods; $^†P<0.05$ compared with the period of PEEPi application.

observed in each patient to the dependent lung significantly increased $Pa_{O_2}$ to 16.0 (4.0) kPa, $Do_2I$ to 552 (144) ml $min^{-1}$ $m^{-2}$ and RVEF to 38 (8) % ($P<0.05$), and significantly decreased $\dot{Q}s/\dot{Q}t$ to 23 (7) % ($P<0.05$), without altering CI (3.39 (0.81) litre $min^{-1}$ $m^{-2}$) or PVRI (220 (58) dyn s $cm^{-5}$ $m^{-2}$).

In contrast, compared with values during application of PEEPi, external application of PEEPi plus 5 mm Hg to the dependent lung during OLV increased $\dot{Q}s/\dot{Q}t$ to 28 (6) % and PVRI to 286 (109) dyn s $cm^{-5}$ $m^{-2}$ ($P<0.05$) and decreased $Pa_{O_2}$ to 11.5 (1.7) kPa, CI to 2.75 (0.86) litre $min^{-1}$ $m^{-2}$, $Do_2I$ to 436 (120) ml $min^{-1}$ $m^{-2}$ and RVEF to 33 (9) % ($P<0.05$). As a result, this intervention restored $Pa_{O_2}$, $Do_2I$, $\dot{Q}s/\dot{Q}t$ and RVEF towards values during OLV with application of ZEEP to the dependent lung (fig. 1), but decreased CI and increased PVRI compared with values during application of ZEEP or PEEPi ($P<0.05$).

## Comment

PEEPi is most likely to exist when airway resistance is increased or when pulmonary gas trapping or pulmonary hyperinflation occurs.[3 4] We anticipated that PEEPi could appear in the dependent lung during OLV primarily because of high airway resistance from a relatively small endobronchial tube and we demonstrated in this study that this occurred in patients with normal pulmonary function. Blood flow to the non-dependent lung is reduced during OLV in the lateral position by force of gravity, surgical compression and hypoxic pulmonary vasoconstriction.[5] Although the precise mechanism(s) for the development of PEEPi during OLV in the lateral position has not been fully elucidated, it seems likely that the development of PEEPi during OLV was caused by the high resistance of the single lumen through which one lung was allowed to empty, slowing expiratory airflow, resulting in incomplete emptying of the lung during expiration. Furthermore, based on our findings that patients with higher PEEPi showed a greater increase in airway pressure, we cannot exclude the possibility that increased blood flow to the dependent lung during OLV compressed peripheral airways, causing further air trapping in alveolar spaces. In addition, end-expiratory occlusion pressures would reflect increased closing pressures in the dependent lung as a result of reduced elastic recoil from downward displacement of the mediastinum.

Manoeuvres recommended to prevent hypoxaemia during OLV include the use of a high inspired oxygen concentration, increased tidal volume, PEEP to the non-dependent lung[1] or dependent lung PEEP.[1 2] However, the beneficial effect of PEEP during OLV remains controversial; some workers found that oxygenation was improved,[5] unchanged[2] or decreased.[1] These divergent results may be explained, at least partly, by the assumption that each patient has her or his own PEEPi value, and the existence of an optimal PEEP for the dependent lung PEEP for each patient is suggested by our results. The most accepted mechanism by which application of external PEEP is thought to be beneficial is that it causes an increase in lung volume at end-expiration (functional residual capacity (FRC)).[5] The increase in FRC contributes to the prevention of airway and alveolar closure at end-expiration. The increase in lung volume and alveolar opening results in increases in lung compliance and the ventilation–perfusion ratio of the ventilated dependent lung. However, if PEEP-induced intra-alveolar vessel compression is widespread because of excessive PEEP, total pulmonary vascular resistance increases and cardiac output decreases.[5] Consequently, intrapulmonary shunt increases and $Pa_{O_2}$ decreases because of diversion of blood flow away from the ventilated dependent lung to the non-ventilated non-dependent lung.[5]

As the minimal PEEP value was reported to be "better PEEP",[6] it seems appropriate to administer the least amount of PEEP necessary to maintain an adequate $Pa_{O_2}$ at a non-toxic $FI_{O_2}$. In this regard, and also for the purpose of maintaining high CI and RVEF, we recommend using a PEEP value equal to the measured PEEPi value. However, we cannot comment on the effects of PEEP values less than PEEPi applied to the dependent lung on oxygenation and haemodynamic state during OLV in the lateral position, as this issue was not examined in the our study. Despite this limitation, because the therapeutic margin of using PEEP to the ventilated dependent lung to increase $Pa_{O_2}$ during OLV is narrow,[5] we suggest that an optimal PEEP value should be close to that actually measured (PEEPi). However, one should be cautious before applying our results to patients with obstructive airways disease.

# Antioxidant potential of i.v. fluids

N. STRATFORD

## Summary

In acute clinical settings where there may be a role for antioxidant therapy, patients receive large amounts of i.v. fluids which may have antioxidant activity. To investigate such effects the antioxidant capacity of nine i.v. fluids was measured (Gelofusine, Haemaccel, 20% mannitol, 4.5% human albumin solution, fresh frozen plasma, aprotinin, *N*-acetylcysteine and two hydroxyethyl starch solutions). Results are expressed as mean mmol litre$^{-1}$ Trolox equivalents. Mannitol 20% and the hydroxyethyl starch solutions had no antioxidant activity. Protein-containing solutions (gelatins, albumin and aprotinin) had antioxidant activity 50–66% that of plasma: Gelofusine 0.85 mmol litre$^{-1}$; Haemaccel 0.78 mmol litre$^{-1}$; 4.5% albumin 0.95 mmol litre$^{-1}$; aprotinin 0.80 mmol litre$^{-1}$; fresh frozen plasma 1.45 mmol litre$^{-1}$. However, none was nearly as potent an antioxidant as the clinical preparation of *N*-acetylcysteine, with an antioxidant activity of 502 mmol litre$^{-1}$. Studies of antioxidant therapy may need to take account of the antioxidant effect of i.v. fluids. (*Br. J. Anaesth.* 1997; **78**: 757–759).

**Key words**
Fluids, i.v.

In critical care settings such as septic shock[1] and during or after the reperfusion injury that occurs with, for example, liver transplantation[2] or cardiopulmonary bypass[3], plasma concentrations of antioxidants have been found to decrease. At the same time, there is evidence of increased oxidant-induced cell damage. This has led to the hypothesis that free radical species (in particular the reactive oxygen species) may play an important pathogenic role in local and systemic inflammatory responses. It follows that antioxidants may have a therapeutic role in such clinical settings. In addition to specific antioxidants, it is likely that these groups of patients receive considerable amounts of i.v. fluids. The chemical nature of these solutions suggests that they themselves may be antioxidants. Some are protein or peptide solutions with amino acid side chains which would be expected to have antioxidant activity.[4] Others are starches with multiple hydroxyl groups which may have potential antioxidant activity.[5]

## Methods and results

The antioxidant capacity of nine fluids was measured using the method described by Miller and colleagues.[4] In brief, this assay relies on conversion of a phenothiazine 2,2-azinobis-(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS) to a long-lived radical cation (ABTS$^{\bullet +}$) by hydrogen peroxide in the presence of metmyoglobin acting as a peroxidase. ABTS$^{\bullet +}$ was produced in a linear manner and the concentration measured by spectrophotometry 10 min after initiation of the reaction. Addition of antioxidants to the assay delays the production of ABTS$^{\bullet +}$ so that there is apparent inhibition of oxidation compared with saline controls. A standard curve was constructed using the water-soluble vitamin E analogue Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid). All reagents were obtained from Sigma (UK), except Trolox which was obtained from Aldrich (UK). Metmyoglobin was purified as described by Miller and colleagues to give a final purity of >90% total haem protein.

A standard curve was plotted as percentage inhibition of ABTS$^{\bullet +}$ formation when Trolox 0.5, 1.0, 1.5, 2.0 and 2.5 mmol litre$^{-1}$ was present compared with controls without Trolox. Ten measurements were made for each point and the mean was used to plot the standard curve. There was an SD of 7% about each point, indicating a precision similar to that in the original description of the method.[4]

The total antioxidant capacity of any fluid (or dilution of it) added in place of Trolox to the assay can be expressed as mmol litre$^{-1}$ Trolox equivalent activity. The fluids studied were Gelofusine (Braun), Haemaccel (Hoerst), 20% mannitol (Baxter), 4.5% human albumin solution (Bio Products Laboratory), fresh frozen plasma (National Blood Transfusion Service), aprotinin (Bayer), *N*-acetylcysteine (Evans) and two 6% hydroxyethyl starch solutions (Dupont and Laevosan).

The antioxidant capacity of each fluid was measured neat except for *N*-acetylcysteine (formulation concentration 200 mg ml$^{-1}$). This was diluted

*Table 1* Mean (SD) antioxidant capacity of nine i.v. fluids

| Fluid | Mean Trolox equivalent (mmol/litre$^{-1}$) |
|---|---|
| Gelofusine | 0.85 (0.12) |
| Haemaccel | 0.78 (0.14) |
| 20% Mannitol | 0 (0.19) |
| 4.5% Human albumin | 0.95 (0.08) |
| Fresh frozen plasma | 1.45 (0.10) |
| Hespan—Dupont | 0 (0 21) |
| Hespan—Laevosan | 0 (0.22) |
| Aprotinin—Trasylol | 0.80 (0.07) |
| N-acetylcysteine | 502 (14) |

to the recommended initial therapeutic concentration of 150 mg kg$^{-1}$ in 200 ml for a 70-kg patient as this is the fluid normally infused. In fact, this solution was so potent that it had to be diluted a further 200-fold with phosphate-buffered saline to fall within the Trolox reference range.

The antioxidant capacity of each fluid was measured 10 times and the results, which appeared to have a normal distribution, expressed as mean (SD). The statistical package used was StatView 4.1 Power PC version for Apple Macintosh computers (Abacus Concepts, Inc).

The results of these experiments are shown in table 1. All protein-containing fluids (gelatins, 4.5% albumin, plasma and aprotinin) had antioxidant activity. The hydroxyethyl starch and mannitol solutions had no antioxidant activity. As would be expected, *N*-acetylcysteine had potent antioxidant activity in this system. The 200-fold dilution had an antioxidant capacity of 2.51 (0.07) mmol litre$^{-1}$, an equivalent of 502 mmol litre$^{-1}$ for the solution used clinically. When the relative concentrations are accounted for, *N*-acetylcysteine 1 mmol litre$^{-1}$ had antioxidant activity equivalent to Trolox 1.56 mmol litre$^{-1}$.

## Comment

The finding that all the protein solutions have antioxidant activity is to be expected. This is because proteins have amino acid constituents with antioxidant activity such as sulphydryl, hydroxyl and carboxyl groups. In the article by Miller and colleagues describing the method used here, evidence was presented that albumin is the largest single contributor to total plasma antioxidant capacity.[4] It has an antioxidant potency equivalent to Trolox and a high plasma concentration compared with other antioxidants, which make up the difference between the measured albumin and total plasma antioxidant capacities. In this study, measurements of total plasma antioxidant capacity, represented by fresh frozen plasma, of 1.45 mmol litre$^{-1}$ agreed with those of Miller and colleagues whose mean value was 1.46 mmol litre$^{-1}$ with a similar degree of variation. This suggests a comparable performance of this assay in our laboratory to the original report.

It is perhaps surprising that the gelatin solutions, Gelofusine and Haemaccel, were nearly as potent as the 4.5% albumin solution. Gelatin consists largely of polyglycine which, because it has only the simplest amino acid side chain (-H) would not be expected to have antioxidant activity. It may be that gelatin modification by succinyl- (Gelofusine) or urea- (Haemaccel) linkage might increase the antioxidant activity. Both urea and succinate, a dicarboxylate, are antioxidants. The similar antioxidant potentials of the gelatin solutions and 4.5% albumin cannot be explained in terms of a higher protein concentration in the gelatin solutions as Gelofusine is a 4% solution and Haemaccel a 3.5% solution.

In common with the gelatin solutions, the clinical formulation of aprotinin has an antioxidant potential which approaches that of 4.5% albumin solution. This may be an additional attraction when used for its antifibrinolytic action during cardiopulmonary bypass.

The finding that the hydroxyethyl starch solutions had no antioxidant activity was not surprising, as starches are relatively inert compared with proteins. Starches do have hydroxyl (-OH) groups which can have antioxidant activity. However, in polyhydroxy compounds, such as starch, they are much less reactive than in monohydroxy compounds[5] which include some potent antioxidants.

Mannitol had no activity in either our experiments or those of Miller and colleagues.[4] In many articles mannitol is claimed to be a potent hydroxyl radical scavenger. If this is so, then it may not be an antioxidant in this particular system where the following reactions are thought to occur:

$$\mathrm{HX\text{-}MbFe^{3+} + H_2O_2 \rightarrow {}^{\bullet}X\text{-}Mb^{4+}\text{-}OH + H_2O}$$

$$\mathrm{2\,{}^{\bullet}X\text{-}Mb^{4+}\text{-}OH + 2ABTS \rightarrow 2HX\text{-}MbFe^{3+} + 2ABTS^{\bullet +} + O_2}$$

Hydrogen peroxide ($H_2O_2$) oxidizes metmyoglobin ($HX\text{-}MbFe^{3+}$) to form ferrylmyoglobin (${}^{\bullet}X\text{-}Mb^{4+}\text{-}OH$), a highly reactive bi-radical, which oxidizes ABTS to its stable radical cation ($ABTS^{\bullet +}$) with regeneration of metmyoglobin. No hydroxyl radicals are formed in this system and therefore a pure hydroxyl radical scavenger would not inhibit these reactions. However, in experiments such as those of Del Maestro and colleagues[6] which are cited widely by authors referring to mannitol as a potent hydroxyl radical scavenger, a mixture of reactive oxygen species was present. Therefore, it is not clear that mannitol is a pure hydroxyl scavenger. There are two explanations for what was observed: either mannitol is not an effective antioxidant (indeed some work from the organic chemistry literature suggests that polyhydroxy compounds such as mannitol would not be potent antioxidants)[5] or that mannitol scavenges reactive oxygen species, but the radical produced is itself highly reactive and contributes to oxidant stress. Whatever the explanation, this must cast doubt on the potential usefulness of mannitol as a therapeutic antioxidant.

As expected, the most potent antioxidant solution was *N*-acetylcysteine which is probably the best available agent to investigate for any therapeutic role. However, being water soluble, it may not be the best agent to protect lipid membranes which are highly susceptible to oxidant-induced injury.

In summary, except for *N*-acetylcysteine, all i.v. fluids investigated had no or only modest antioxidant activity. They are therefore probably of little therapeutic use. However, in clinical studies describing a small antioxidant effect of any therapy, investigators may need to be aware of a possible confounding effect of protein-containing i.v. fluids.

CASE REPORT

# Perioperative use of the oesophageal Doppler probe (ODM II) on a patient scheduled for transmyocardial revascularization

G. DJAIANI AND I. HARDY

## Summary

We describe the use of the continuous wave oesophageal Doppler monitor (ODM II) in the perioperative management of a patient with chronic obstructive coronary artery disease undergoing transmyocardial revascularization (TMR). The use of ODM II allowed both quantitative and qualitative assessment of cardiac function relatively non-invasively. It detected the successful transmyocardial penetration of a laser beam during operation by visual and auditory phenomena in addition to reflecting improvement in cardiac performance after operation. (*Br. J. Anaesth.* 1997; **78**: 760–761).

**Key words**
Measurement techniques, Doppler echocardiography. Complications, coronary artery disease. Surgery, cardiovascular.

Transmyocardial revascularization (TMR) is a new surgical technique that is used in patients with chronic obstructive coronary artery disease that is refractory to conventional revascularization techniques and to maximal medical therapy. In this group of patients with end-stage coronary artery disease the chosen anaesthetic technique should minimize the haemodynamic changes imposed in the perioperative period and be tailored to meet the requirements of the procedure. Perioperative monitoring should provide early detection of haemodynamic changes and indicate the successful transmyocardial penetration of a laser beam during operation. We describe the successful and informative use of the continuous wave oesophageal Doppler (ODM II) in a patient undergoing TMR. The ODM II provides a visual display of the spectral analysis of the Doppler frequency shifts back-scattered from blood flow in the descending thoracic aorta allowing non-invasive assessment of cardiac output, which is provided by minute distance, the product of waveform area (stroke distance) and heart rate.[1] In addition, the device allows indirect assessment of left ventricular filling, contractility and resistance to ejection.[2]

## Case report

A 60-yr-old, 75-kg male, ASA class IV, who had two consecutive coronary artery bypass grafting (CABG) operations but continued to suffer from limiting angina regardless of full medical therapy was offered TMR. After overnight sedation with lorazepam 4 mg he received morphine 10 mg and hyoscine 0.3 mg as premedication. The right radial artery and left forearm peripheral vein were cannulated with 20-gauge and 14-gauge cannulae, respectively, under local anaesthetic. Anaesthesia was induced with propofol 100 mg (as an infusion over 3 min) and alfentanil 1.5 mg. After neuromuscular block with atracurium 50 mg, an ODM II Doppler probe was placed in the oesophagus and a large left-sided Robertshaw double lumen tube was positioned and the lungs ventilated with an air–oxygen mixture. Baseline cardiac index was 2.5 litre $m^{-2}$ $min^{-1}$. A central vein was cannulated via the right internal jugular vein using a triple lumen catheter. An extradural catheter was then sited at the mid-thoracic level (T6–7) and pain relief was produced with an infusion of 0.125% bupivacaine and fentanyl 5 $\mu g\ ml^{-1}$ at a rate of 5 ml $h^{-1}$ via the extradural catheter after an initial bolus dose of 7 ml of the solution before surgery. Anaesthesia and neuromuscular block were maintained with propofol 3 mg $kg^{-1}$ $h^{-1}$ and atracurium 0.5 mg $kg^{-1}$ $h^{-1}$ infusions, respectively. Standard monitoring was used, including $F_{I_{O_2}}$, ECG, pulse oximetry, direct arterial and central venous pressures, and ventilatory variables.

After a left anterior thoracotomy, one lung ventilation was commenced and the heart was exposed. Holes were drilled through the ischaemic myocardium by the laser beam and confirmed by the ODM II with visual (showers of ultrasound echoes) and auditory "whoosh" phenomena. A total of 22 holes were made. The patient tolerated the procedure well and his trachea was extubated immediately after surgery. He was then transferred to the intensive care unit. The patient was monitored closely in the postoperative period and remained haemodynamically stable with adequate gas exchange. The extradural infusion was continued for 24 h. He was pain free and felt subjectively improved. The Doppler probe was left *in situ* for 8 h after operation

and cardiac index was recorded continuously for that period. Cardiac index remained increased from baseline and varied from 3.9 to 4.5 litre $m^{-2} min^{-1}$. The probe was removed after 8 h as the patient started taking fluids.

## Discussion

It has been shown that producing small holes in the ischaemic myocardium by a laser beam improves functional status and offers a ray of hope for these sick patients.[3] During operation, which is performed on the beating heart through a left thoracotomy, a high energy laser is used to bore transmural channels into the left ventricle so that blood flows directly from the left ventricle into the channels and then into the myocardial vascular plexus.[4] Restoring perfusion should alleviate ischaemia in a potentially viable myocardium and improve ventricular function. Postoperative thallium stress tests and left ventriculography indicate that the channels remain patent and protect the ischaemic muscle. There has been anatomical evidence of patent endothelialized channels which contained red blood cells suggesting that the laser channels were functional.[5]

A trans-oesophageal echocardiography (TOE) probe has been used in the past. It requires an additional medical person trained in TOE, it is not tolerated by an awake patient after operation and is costly. We suggest that the use of a continuous wave oesophageal Doppler probe can prove very useful in the intraoperative detection of flow turbulence during successful puncture and assessment of cardiac function in the immediate postoperative period. It is much smaller in size and tolerated better than a TOE probe by an awake patient after operation. The probe is positioned in the lower third of the oesophagus. An indication of which is the "best" signal can be assessed from the one with the highest peak velocity (PV). The ultrasound beam is reflected from the red blood cells travelling in the aorta and the resultant change in frequency is picked up by the probe and relayed to the monitor which calculates the velocity of blood in the descending aorta and from this calculates stroke volume, cardiac output and other associated variables in real time and for each heart beat. There is a signal quality bar which allows determination of whether the quality of the signal has changed as the probe was positioned. The correct signal has a very clear systolic pulse with a very low or totally absent diastolic flow. There is potential for movement artefact when the quality of the signal changes, for example if the patient's position is changed it is possible to pick up a signal from venous and intracardiac sources, but these are easily recognized and corrected. The spectral waveform gives an indication of linear movement of blood in the aorta. To change these data from linear into volumetric, the computer uses a conversion table based on the age, sex and mean arterial pressure of the patient to produce a volume conversion factor (K) for that patient. This is multiplied by minute distance (MD) which is acquired from multiplying heart rate and stroke distance (distance moved by a column of blood for one cardiac cycle). This is used to produce continuous cardiac output (CO) data ($CO = MD \times K$ in litre $min^{-1}$). It was noted that cardiac index doubled and sometimes tripled immediately after successful penetration for approximately 1 min.

Animal data suggest that TMR is an alternative method of treating ischaemic heart disease in terms of both short- and long-term improvement in myocardial contractility and also for the diminished area at risk from necrosis.[6] The optimum number of transmural channels per area, spacing and placement of channels, and contribution of the channel to overall perfusion still need to be quantified. Although it is too early to draw any conclusions it may be that the creation of transmyocardial channels increases cardiac index by improving the inotropic function of the myocardium in the immediate postoperative period. Previous studies have shown that estimation of cardiac output can be made to approximately 90% accuracy with a considerably lower coefficient of variation[7] compared with a standard thermodilution method.

As TMR is taking its place in the treatment of patients with chronic obstructive coronary artery disease, we believe that the use of the ODM II in the perioperative period is a simple, reliable and useful guide for detection of successful penetration of an ischaemic myocardium. It is a good guide for measurement of cardiac output in the perioperative period and is minimally invasive providing flow-based rather than pressure-based monitoring.[8]

COMMENTARIES

# Toward the paperless hospital?

R. H. R. HARPER, K. P. A. O'HARA, A. J. SELLEN AND D. J. R. DUTHIE

**Summary**

This report describes an ethnographic study of document use by anaesthetists. In doing so, it focuses on the role of the preoperative risk assessment form as used in anaesthetic practice at a cardiothoracic hospital, and considers what would be the advantages and disadvantages of shifting the paper into the electronic form. Evidence from this case study is used to comment on how the practical use of documents by medical professionals can be fundamentally at odds with how the organization at large would like to use them. We argue that hospital trusts need to take into account this practical perspective in order to build effective, on-line document systems. (*Br. J. Anaesth.* 1997; **78**: 762–767).

**Key words**
Records, anaesthesia. Records, anaesthesia, computerized. Computers. Anaesthesia, audit. Anaesthetists, activity.

Hospitals, in common with most other organizations, depend on a wide range of documents for the day-to-day accomplishment of work. These documents take on a myriad of formats, both paper-based and computer-based. With advances in digital technologies, there are many pressures to do away with what is often perceived to be the unnecessary clutter and cost of paper documents. There is a common perception that improved efficiency and productivity can be gained by transferring information "on-line" to take advantage of computer-based tools.

We report on a study of anaesthetic practice, the purpose of which was to understand the practical aspects of document use in a medical organization, and the implications of paper documents moving "on-line". The method reported is based on "sociological ethnography", a branch of sociology which developed from a social anthropological tradition that involved "ethnographers" spending long periods of time closely observing small scale societies. This approach has been developed for the observation of social behaviour within any and all institutions. It involves observation of work and activities in their "natural" setting, in addition to extensive interviewing. As such, it offers an "outsider's" perspective on anaesthetic practice and document use.[1]

For this case study, we chose to focus on anaesthetists because the research team already had some background knowledge and experience in studying anaesthetic practice.[2–4] The hospital which we selected for the study is a cardiothoracic hospital where there is a desire to take advantage of new technology in developing its document practices.

While we considered all of the key documents that anaesthetists in this hospital use, we were concerned mainly with the *preoperative risk assessment (PRA) form* which was designed within the study hospital. Although not every hospital trust uses such a form or even ones that are similar, we focused on this form because it contains the most extensive set of anaesthetic relevant data and, as such, is seen as potentially a useful resource for organizational purposes such as auditing and assessing preoperative risk. Indeed, one of the general purposes of the PRA form when it was first introduced was that it would contain data which would be useful for audit purposes and risk stratification. The information contained in the forms could then be used to calculate various statistical scores, such as UK ACTA (UK Association of Cardiothoracic Anaesthetists) and Parsonnet.[5]

However, this hospital has experienced two major obstacles to using the data in this way. First, the PRA forms tend to be filled out inadequately, making analysis difficult. Second, the data are in paper form and therefore need to be entered manually into the electronic system. Currently, the paper forms are sent to a central store in theatre reception so that the data can be entered later into a computer. However, for the most part, the paper remains in store and no major effort, to date, has been made to use the data.

The PRA form therefore represents an interesting case of a document which, while now well established in use in this particular hospital, is seen to fall short in terms of serving its original purposes. As it happened, it was also a particularly opportune time to conduct the study as a new electronic alternative to the paper PRA form was about to be introduced.

Although this is a study of the use of one particular type of form in one hospital, we believe that findings from this study can be applied to medical document systems at large. The case of the PRA form illustrates how the practical use of documents

by medical practitioners can sometimes be fundamentally at odds with organizational aims and purposes. We discuss the reasons why, and argue that these practical issues need to be taken into account in order for medical document systems to effectively move forward.

## Methods

There are a variety of ways that document-related activities can be investigated. For example, one standard procedure is to conduct a time and motion study of document use. However, this type of technique overlooks the motivations that underlie people's activities, and the particular perspective that professionals take toward their work. One technique that can capture these concerns is sociological ethnography. This approach involves close observation of work as it occurs *in situ* and extensive open-ended interviews.

In this study, the ethnographic approach was used to understand the ways in which anaesthetists responded to the particular circumstances in which they found themselves, and the practical concerns that they brought to their work. Throughout, the focus was on how documents—and the PRA form in particular—played a role in this work. The study took place over a period of 5 days. Specifically, this ethnographic approach involved:

(1) Observing anaesthetists at all stages of their work, from patient interviews to the operating theatre to the recovery unit.

(2) Examining what was done with the PRA form during its entire life cycle. This began at the point where anaesthetists were observed going through patients' files at the ward reception, and ended with observing their postoperative use.

(3) Undertaking interviews with trainees and consultants about their work. When possible, these interviews focused on particular examples of PRA forms which were in the process of being completed.

These activities generated a detailed picture of the work in question, and in particular the practical, "real world" orientation of anaesthetists.

## Results

The ethnography found that, from the anaesthetist's perspective, the PRA form had a significant role within two main stages of the work: during the interview with the patient and in the anaesthetic room.

The patient interview stage, normally undertaken on the day before an operation, can be characterized as an information gathering stage with the PRA form serving as an information repository. Most of the information to be entered on the form is prespecified, but some is also added in the form of free-hand notes. While information is also obtained from the patient's notes at this stage, much of it can be gathered only from the patient during the interview (for example NYHA status, dentition and drug allergies).

In its role as an information repository, the PRA form serves three main purposes. The first is to enable the anaesthetist to think about and plan the anaesthetic during the operation on the following day. The second is to enable the anaesthetist to write notes to serve as reminders during the impending operation. (Such reminders are especially important given that anaesthetists may manage several anaesthetics during a list.) The third purpose is to enable the "handing over" of an operation to another anaesthetist should the need arise. Because of the volumes of work and the fact that the workload cannot always be predicted, it is not always possible to ensure that the person who interviews a patient is also the one managing the operation.

During the second phase—in the anaesthetic room—the PRA form is used mainly as a reference source before induction of anaesthesia. It is here that free-hand, written reminders can be critical to the smooth management of the anaesthetic, and it is here that a colleague's notes taken during the patient interview serve their purpose.

For the anaesthetist, when anaesthesia is induced, the PRA form remains available but has effectively come to the end of its useful life. In terms of documents in the operating theatre, the anaesthetist turns his or her attention primarily to completing the anaesthetic record. It is unlikely that the anaesthetist will look at the PRA form again, although sometimes the surgeons or other operating theatre staff may do so.

This description helps to make clear the practical role of the PRA form. For these anaesthetists, the PRA form serves as a unitary repository of information and reference tool. As such, our observations confirmed that this paper document is not only adequate, but is a useful practical tool in facilitating anaesthetic work.

However, our observations also confirmed that, for organizational purposes (i.e. data for computing UK ACTA scores or for carrying out organizational audits), there are two ways in which the forms are inadequate or problematic: the data on the forms are incomplete and there are difficulties in transforming the paper-based data into electronic data.

### PROBLEM OF INCOMPLETE DATA

If the information on the PRA form is examined in detail, it is apparent that there are almost always missing data. Indeed, of the 517 PRA forms we had at our disposal, none contained complete information. We also found that most consultants never filled out a PRA form. Of the three consultants we observed that did so, two filled out only 10 of the 517 forms. We learned that most consultants prefer to delegate this job to trainee staff. Consultants still use the forms to manage operations, but they use their junior colleagues' PRA forms. A by-product of this is that the consultants' practice is in part undocumented and it is only the trainees whose assessments are recorded.

We believe that the salient issue here is not who fills out the form but the relationship between documents and how they are used. Why are the data so incomplete? One reason often cited by hospital trust managers, systems designers and other commentators on hospital life is that anaesthetists (in

*Figure 1* Example of a preoperative risk assessment (PRA) form.

common with any group of professionals) are simply unwilling to fill out forms correctly. We believe, however, that this is to misunderstand the issues. On closer inspection of the PRA forms and the associated work practices, there are at least two good reasons why PRA forms show absence of information. The first is related to the fact that anaesthetists adapt the PRA form in such a way as to transform a form designed for *general purposes* into one that is useful for *specific purposes.* In other words, anaesthetists treat the PRA form as a device that enables them to gather information that they need for that particular operation, and not as a device for the gathering of information for generalized use—whether it be for *post hoc* analysis or administrative audit. By way of example, a copy of a real form is shown in figure 1, altered only in order to disguise the identities of the patient and anaesthetist. Most of the fields in the section labelled *Diagnosis*, are blank; all the fields under the section *Results from Notes* have not been completed.

The reason for the lack of data is the fact that in *this* case, for *this* operation and for *this* patient, the information requested in those sections was not as relevant. This patient was about to have an operation on an incisional hernia. Previous cardiac surgery had provided symptomatic benefit and there had been no subsequent cardiac catheterization. For these reasons, the anaesthetist made the judgement that, from his point of view, it was not worth the effort of entering the information on the form.

This does not mean that the form was of no use. This example shows that what is omitted may be as informative as what is completed. In this example, the anaesthetist has written in the operation being undertaken. Concerns which were relevant for this operation were then remarked upon, in this case in the section marked *Specific Patient Queries.* Therefore, questions on allergies, history of hypertension, and so on, were answered. Thus, if another anaesthetist needed to refer to this form, they would be able to know the areas of concern by seeing what operation was scheduled. In this respect, the form is filled out *correctly*, that is providing information that anaesthetists need in the course of their work.

One could argue that the form in figure 1 is simply inappropriate for this particular operation, or that this is an exceptional case. However, we found that this case exemplifies, although perhaps exaggerates, how all PRA forms are used.

The second, perhaps more mundane, reason for incomplete data is that, in some situations, the information anaesthetists require is not available. Patients' notes are often so extensive that it makes information difficult, if not impossible, to find. Different wards often have their own ways of organizing a patient's file and the patient's previous hospital may have different standards of record keeping. This too can make it difficult to find facts. Often the cost in time and effort of prolonged searches for information may not justify the small benefits to be obtained from certain types of information (e.g. height).

Further, some information, although ideally important for the anaesthetists, may not be available when the form is filled out. An example of this type of information is blood test data: haemoglobin counts are very useful to anaesthetists but may not be available when they undertake the patient interview.

Taken as a whole, these considerations could indicate that there are good reasons for PRA forms to be somewhat bad clinical records—bad in the sense that they are never filled out completely (cf. quality of records in mental health agencies).[6] However, to think of them in this way is to ignore the fact that these forms are useful for anaesthetists in that they record local knowledge and needs, and reflect the requirements of each particular case.

### USE OF PAPER

The second major obstacle to organizational use is that the PRA data are paper-based and need to be entered manually into the computer system. Our observations confirmed that, in the face of many other more pressing demands, the rather tedious job of entering this information into the system was not a high priority. Consequently the data were not transferred.

What might be the impact of replacing the paper PRA system with a computer-based PRA system? In order to assess this, we first need to consider in more detail the ways in which the paper form serves important functions in the various phases of anaesthetists' work. There were three main advantages to the use of paper that we observed.

#### *(1) Flexibility of paper*

We have already seen that the task of filling out the PRA form through consultation of patients' notes may result in omitting information either because it is not always important to a specific case or because it is not always available. Because it is a paper form, this allows a flexibility of completeness whereby only the relevant information for that particular patient is recorded. Free text annotation is also easy with paper and thus short explanatory notes and reminders can be added to the form. This type of information cannot be expressed easily within the constraints of a structured on-line form. The paper form is thus highly flexible.

#### *(2) Non-disruptive nature of paper*

Related to the flexibility issue is the fact that paper is a medium that supports non-intrusive ways of taking notes during a patient interview because it can be marked directly in a relatively unconstrained way (cf. the process of general practitioner–patient interviews).[7] Thus note taking can be interweaved easily with the ongoing discussion. This is important because the patient interview is not simply about obtaining information from the patient. It can often be a delicate social activity which is there to help make the patient feel more comfortable about the nature of the operation and to personalize the situation for both the patient and anaesthetist. At present, paper supports this process because it allows attention to be devoted to the management of the interview.

#### *(3) Portability of paper*

A third set of issues relates to the fact that paper is portable and that its contents are quickly accessible. These properties are important in all stages of the life of the PRA form. It is important during preparation of the PRA form in conjunction with the patient's notes because it is sometimes the case that the forms are filled out away from the busy ward rooms. At the bedside, the portability and accessibility of the paper PRA form is important in supporting the patient interview process. With paper, anaesthetists can make use of a clipboard resting on their knees. Portability is also beneficial between operations: sometimes the anaesthetist may consult the PRA form while moving between different operating theatres in preparation for a new patient.

## Discussion

### IMPLICATIONS FOR MOVING ON-LINE

From this case study, we have seen that the PRA form is an example of a medical document which is tailored in accordance with the practical realities and idiosyncrasies of each case. As a result, this often implies that data are missing and forms are incomplete. We have also discussed the ways in which the fact that the paper PRA is flexible, non-disruptive and portable can make it a very useful device in support of the work practices of medical professionals. Both facts militate against efforts to aggregate the data on-line and use it for statistical analysis.

Yet there are many potential benefits to moving to an electronic PRA system. As we have already discussed, from the Trust's point of view, there are the benefits of the reduced cost of storage space, and of using a format that allows aggregation of data and on-line analysis. With regard to the problem of incompleteness, a technological alternative could force anaesthetists to be more complete by requiring them to fill out every field, and by preventing them from bypassing fields until data are entered.

This is not to say that electronic document systems need necessarily always work to the benefit of Hospital Trusts and to the detriment of medical professionals. Electronic access to data may be very advantageous to practitioners in the course of preparing and referring to a medical form. It may help to eliminate much of the redundant form-filling activity that currently occurs with paper forms by linking to a centralized data store. It may solve problems of accessing and retrieving data that are otherwise difficult to find among paper notes, or which are generated by different departments or hospitals. It can help in ensuring that data are as up-to-date as possible. It could also provide remote access to information. At the present time, some consultants obtain information read to them over the phone by trainees. The introduction of digital technologies could offer networked access to the forms. This would have at least two advantages: first, it would release trainees from making phone calls to their superiors; second, it would allow consultants to access information when and where they need it (e.g. from home or from another hospital).

However, designing such systems is challenging. We have discussed the importance of the flexibility, markability, portability and accessibility of the paper PRA form. Most current electronic document systems tend to provide more structured and constrained interfaces, require indirect forms of input via keyboards, are relatively immobile and are cumbersome to navigate. Added to this are problems of screen size, viewing angle and the ability to share multiple documents concurrently by people in the same room.

The new electronic system now in place in the hospital we studied suffers from many of these problems. Perhaps unsurprisingly, therefore, the paper PRA form continues to be used throughout its "natural life cycle" from the ward room to the operating theatre for all the reasons that we have outlined. Anaesthetists then enter the data from the paper PRA forms into the new electronic system, usually during the course of an operation. This means that the paper PRA form continues to be the useful artefact for the anaesthetist. Entering the information electronically simply resuscitates the document after its "organizational death". The new system therefore does not directly support the day-to-day activities of the anaesthetists, but is an additional activity that is required purely for purposes outside the local concerns of the practitioner. The success of the system therefore relies primarily on a "moral obligation" on the part of the anaesthetists to complete the form, rather than on good clinical reasons to do so.

The question, then, is whether one can devise electronic document systems that concurrently serve the purposes of *both* the medical practitioner and the organization at large. Such a technology would have to be suited for all stages of the life cycle of the PRA form. For the first stage, the patient interview, the device would have to allow ease of navigation, incompleteness of data entry and free text entry. One way of providing these features is to offer a relatively unconstrained interface; another is to allow more direct input via electronic stylus devices, for example.

The electronic alternative to the paper PRA form must also have the flexibility to be used not just at the bedside, but in the ward rooms, in the anaesthetic room, in the operating theatre or even moving between theatres. It must not be affected by the constraints imposed by these environments. For example, at the patient's bedside there are no desks or supporting surfaces. This may make even lightweight portable computers cumbersome to use. Other considerations include poor lighting conditions, which suggests the need for good displays which are legible at a range viewing angles.

Finally, in the anaesthetic room and the operating theatre the technology must not hinder staff accessing various documents concurrently. Therefore, a technological solution which provides only one display screen for access to the PRA form and other documents may be problematic (although this could be managed by users "taking turns" for screen access).

For all of these reasons, we believe an effective technological alternative to the paper-based PRA form requires careful design and iterative testing in a real work setting. These requirements also suggest that the best design options will rely on new technologies that are currently still in their developmental infancy (e.g. portable, wireless computing, pen input and lightweight, high resolution screen technologies). In the meantime, an alternative approach is to accept the fact that paper is a tool that is extremely useful for some types of medical documentation including the PRA form, at least in the foreseeable future. This approach involves: (1) distinguishing between those types of medical documents which are best kept as paper and those which are best transferred to the digital realm; (2) concentrating on technologies which bridge the paper and electronic world, such as scanners; and (3) investigating and developing further those technologies and techniques that bring further "intelligence" to these scanning technologies through the use of such procedures as bar coding to facilitate document identification and tracking.

With regard to (2) and (3), this implies viewing such technologies not simply as a way of dealing with the legacy of paper, but rather as a way of supporting an ongoing mix of paper and electronic media.

Any of the above approaches requires a comprehensive understanding of the work practices of medical professionals in relation to the documents they use. In particular, they require an understanding of how practical requirements of medical practice can lead to the use of documentation that is not ideally suited for generalized consumption and use. Changes can be brought about in these practices with the introduction of new technologies, but must not be at the expense of the requirements of clinical professionals. In this article, we hope to have demonstrated one approach which is capable of uncovering what those practical concerns may be, and their implications for the design of new document technologies. Further use of this approach will, we suggest, lead to decisions about investment in electronic or in mixed paper and electronic document systems that are based on more accurate appraisals of the balance between the local, practical needs of medical professionals and those generalized needs of NHS Trusts as a whole.

# Guidelines for autologous transfusion. II. Perioperative haemodilution and cell salvage

BRITISH COMMITTEE FOR STANDARDS IN HAEMATOLOGY BLOOD TRANSFUSION TASK FORCE: J. A. F. NAPIER (CHAIRMAN), M. BRUCE, J. CHAPMAN, J. K. M. DUGUID, P. R. KELSEY, S. M. KNOWLES, M. F. MURPHY, L. M. WILLIAMSON AND J. K. WOOD
Drafted by the Autologous Transfusion Working Party: D. LEE (CHAIRMAN), M. CONTRERAS, N. CROSS, M. J. DESMOND, J. GILLON, A. LARDY AND F. G. WILLIAMS

## 1. Introduction

Part I of the Guidelines for Autologous Transfusion dealt with preoperative autologous donation and was published by the British Committee for Standards in Haematology (BCSH) Task Force in 1993.[1] Part II deals with acute normovolaemic haemodilution in the perioperative period and red cell salvage procedures.

The purpose of all forms of autologous transfusion is to avoid the transfusion of allogeneic blood. This may be necessitated, for instance, by difficulty in obtaining compatible blood for a particular patient, for example when the patient has a rare blood group or when multiple red cell antibodies are present, but more commonly is used as a general strategy for avoidance of the risks (infectious and immunological) of allogeneic transfusion. Autologous transfusion procedures are not usually acceptable to Jehovah's Witnesses, although some accept intraoperative cell salvage (see below). The option must be discussed with patients individually.

In order to maximize the potential benefits, the various forms of autologous transfusion should be seen as complementary, and it is essential that an appropriate transfusion strategy should be developed for each individual patient's needs. Co-ordination of autologous transfusion procedures is of vital importance, with clear methods for communicating whether pre-deposited autologous blood is available as it may be unnecessary to use additional autologous techniques in some patients. It must be remembered that the serious risks of allogeneic transfusion are lower in the UK than in many other countries, and that the procedures used for autologous transfusion of whatever type must be considered carefully so as to minimize potential adverse effects of the procedure itself. The decision to transfuse the autologous blood should be based on that particular patient's need for blood, rather than simply on its availability.

Specific consent for autologous transfusion procedures carried out in theatre is not considered to be necessary. Currently this requirement is considered to be covered by generic surgical consent, although patients must be given full information about the proposed treatment. The information sheet should state that it may be necessary to administer allogeneic blood in an emergency.

While these guidelines seek to deal with situations likely to be met in current clinical practice it is recognized that exceptional circumstances may arise and that the final decision regarding the use of autologous transfusion rests with the consultant (or deputy) who undertakes the procedure.

## 2. Acute normovolaemic haemodilution

1. Acute normovolaemic haemodilution (ANH) is defined as the removal of blood from a patient immediately before operation, either before or shortly after induction of anaesthesia, and simultaneous replacement with an appropriate volume of crystalloid or colloid fluids, alone or in combination, such as to maintain the circulating volume.

The risks of haemodilution (i.e. of a low intraoperative haematocrit) can be minimized by limiting its extent (target haematocrit 25–30%); however, studies using mathematical modelling techniques suggest that savings in allogeneic blood use in such circumstances are likely to be small. Prospective controlled studies are needed to elucidate the effectiveness or otherwise of moderate ANH in reducing the need for allogeneic transfusion.[2]

Extreme haemodilution (target haematocrit <20%) is likely to be more efficacious in reducing allogeneic transfusion requirements, but the risks are correspondingly greater. This procedure should be restricted to relatively healthy patients with a low risk

---

Address for correspondence: BCSH Secretary, British Society for Haematology, 2 Carleton House Terrace, London SW1Y 5AF.

of ischaemic heart disease and must be supervised by an expert anaesthetist using appropriate monitoring techniques.

A degree of haemodilution is inevitable in patients on cardiopulmonary bypass unless a blood prime is used; this must be taken into account when additional haemodilution is undertaken.

2. Preoperative apheresis to obtain autologous platelets/FFP/red cells should currently be viewed as a research technique, the benefits of which are not proved. These techniques cannot yet be considered to have a place in routine practice.

3. ANH may confer benefits other than those implied by the avoidance of allogeneic transfusion, for example reduction in red cell loss during operation (secondary to reduced haematocrit) and improved oxygen delivery (secondary to reduction in whole blood viscosity). The availability of blood containing normal concentrations of coagulation factors and functioning platelets for transfusion at the end of the procedure is of theoretical benefit. There is no evidence that these factors confer measurable clinical benefit.

4. The decision to recommend ANH for an individual patient should lie with the anaesthetist and surgeon. The responsibility for the procedure itself normally lies with the anaesthetist. The involvement of the haematologist in charge of the blood bank is to be encouraged, both in developing transfusion strategies and in assisting with the production of standard operating procedures. Where appropriate the consultants in the local transfusion centre should be invited to assist in the training of staff and the production of SOPs.

## 5. SELECTION OF PATIENTS

ANH should only be considered when the potential blood loss is likely to be greater than 20% of blood volume. ANH should not be considered unless the preoperative haemoglobin concentration is $>110$ g litre$^{-1}$. Although the risk of complications relating to unsuspected atheromatous disease, particularly silent myocardial ischaemia, increases with age, patients of any age may be considered for the procedure. Particular caution should be exercised in patients more than 45 yr of age in the assessment of the risk of underlying ischaemic heart disease, and in patients with severe diseases of other systems.

Patients with severe myocardial disease of any cause, for example moderate to severe left ventricular impairment, unstable angina, severe aortic stenosis, critical left main stem disease or the equivalent, should only undergo haemodilution over and above that necessarily incurred during cardiopulmonary bypass with extreme caution.

6. Patients undergoing ANH need not be screened routinely for viral markers. Universal precautions to protect staff from the risks of virus transmission must always be observed. The used container and giving set must be disposed of in accordance with the hospital policy for the disposal of hazardous waste; the fate of all units must be documented.

## 7. PROCEDURES

A suggested operating procedure is outlined in appendix 1.

The safety of ANH depends on the maintenance of normovolaemia. In all patients, care must be taken to match the continuous replacement of volume with the removal of blood. In older patients and where cardiac disease may be suspected, additional care is necessary.

Appropriate blood collection packs must be used to ensure a standard anticoagulant/blood ratio. The approximate volume of blood to be removed (in litres) to achieve the desired haematocrit can be calculated using the following formula:

$$V = \mathrm{EBV} \times (\mathrm{H}_0 - \mathrm{H}_f \,/\, \mathrm{H}_{av})$$

where $V$=volume to be removed, EBV=estimated blood volume (usually taken as 70 ml/kg body weight), $\mathrm{H}_0$=initial haematocrit, $\mathrm{H}_f$=desired haematocrit and $\mathrm{H}_{av}$=average haematocrit (mean of $\mathrm{H}_0$ and $\mathrm{H}_f$).

8. (i) *Labelling.* All units must be labelled with the patient's name, hospital number, date of birth, date and time of collection, and the name of the person carrying out the procedure. The label must be clear, and should state "UNTESTED BLOOD: FOR AUTOLOGOUS USE ONLY". Pre-infusion checks of identity are mandatory and should be equivalent to the hospital's standard procedures for administration of allogeneic blood.

(ii) *Storage.* Blood removed during haemodilution must remain with the patient and should not be removed to a blood fridge. It may be kept for up to 6 h at room temperature, preferably in an insulated box or other container to minimize temperature fluctuations. The container should be labelled with the patient's full details with a warning that it must not be used for another patient.

(iii) *Disposal.* In general all such blood should be used in theatre. If ANH blood is transported with the patient to a recovery area or ward, a written procedure should be in place to ensure that the blood is handled and administered to the patient according to the standards outlined in (i) and (ii) above. Blood from patients known to have markers for viral infections (HIV, HBV, HCV) must not be allowed to leave theatre unless the infusion has already commenced.

Any unused autologous blood is to be disposed of as hazardous waste, preferably in theatre; the fate of all units must be documented. These procedures should be included in a local standard operating procedure which should also include instructions to ensure that no autologous blood is transferred to the general blood supply.

9. The number of units of blood and total volume removed from the patient must be recorded in the patient's case notes. Where allogeneic blood is given, the reasons must be documented clearly in the patient's notes.

10. Serious adverse events should be reported to the hospital transfusion committee and to any appropriate national reporting system.

11. Regular audit of procedures should be undertaken under the aegis of the hospital transfusion committee. Audit and comparison with allogeneic blood usage would be facilitated by the routine recording of autologous blood use in theatre.

## 3. **Red cell salvage**

1. The indications, contraindications, potential adverse effects and range of methods of red cell salvage are described in appendix 2.

2. A designated member of the consultant medical staff must be responsible for training and supervision of the staff carrying out cell salvage procedures.

### 3. SELECTION OF PATIENTS

Cell salvage is appropriate where there is a clean wound. The technique is applicable to open heart surgery, vascular surgery, total joint replacements, spinal surgery, liver transplantation, ruptured ectopic pregnancy and some neurosurgical procedures. Some Jehovah's Witnesses may accept transfusion of autologous cells salvaged by a continuous circuit device: specific consent to the procedure should be sought in this instance.

### 4. CONTRAINDICATIONS

Cell salvage techniques should not be used in the presence of bacterial contamination of the operative field. Malignant disease has been considered a contraindication but recent published work suggests that the risk of dissemination of malignant disease is minimal. Blood containing fat or amniotic fluid should not be salvaged because of the risk of embolism and DIC. Topical clotting agents such as collagen, cellulose, gelatine and thrombin, and topical antibiotics or cleansing agents used in the operative field should not be aspirated into a cell salvage device. Complications have been reported in patients with sickle cell disease.

5. Patients undergoing cell salvage need not be screened routinely for viral markers. Universal precautions to protect staff from the risks of virus transmission must always be observed. The used container and giving set must be disposed of in accordance with the hospital policy for the disposal of hazardous waste.

6. All blood salvage devices should be used in strict compliance with the manufacturers' instructions. The responsible consultant must ensure that a designated person is responsible for the maintenance of equipment, adherence to SOPs and documentation of all procedures.

7. Blood for reinfusion must be labelled according to the specifications given for ANH. Labelling, storage and disposal of salvaged blood must be in accordance with the standards outlines in paragraphs 2.8 above.

8. All cell salvage procedures and volumes of blood reinfused must be recorded in the patient's case notes. Where allogeneic blood is given, the reasons must be clearly documented in the patient's notes.

9. Serious adverse events should be reported to the hospital transfusion committee and to any appropriate national reporting system.

10. Regular audit of procedures should be undertaken under the aegis of the hospital transfusion committee. Audit and comparison with allogeneic blood usage would be facilitated by the routine recording of autologous blood use in theatre.

## Appendix 1

### "BLOOD COLLECTION"

The following points are important in collecting blood during preoperative haemodilution.

1. Blood may be collected into a single pack with CPD-A1 anticoagulant. (Licensed blood packs for collection of approximately 450 ml ±10% or 250 ml ±10% are available. Appropriate pack size selection is important to maintain anticoagulant to blood ratios. Some manufacturers may make dedicated packs.)

2. A regularly calibrated balance should be used to measure the volume of blood drawn.

3. Skin should be cleaned thoroughly using chlorhexidine (in alcohol) or equivalent.

4. The donor tubing should be clamped, for example with "non toothed" Spencer Wells forceps, before the guard is removed from the needle. The clamp should remain in place until after the venepuncture. This prevents air entering the bag and possibly contaminating the donation.

5. The blood pack should be labelled during donation.

The label affixed to the blood pack should include the following information:

Surname

First names

Date of birth

Hospital number

Date and time of collection

Responsible Medical Officer

UNTESTED BLOOD: FOR AUTOLOGOUS USE ONLY

6. The pack should be agitated gently throughout collection to mix the blood with the anticoagulant.

7. The bleed line should be sealed with clips or a heat sealer both at its cut end and close to the pack.

## Appendix 2

*Table 1* Indications, contraindications, potential adverse effects and methods of red cell salvage

| Technique | Indications | Contraindications | Potential adverse effects | Comments |
|---|---|---|---|---|
| Acute normovolaemic haemodilution | Elective surgery with expected loss >20% TBV | Aortic stenosis, unstable angina, left main stem disease or equivalent, moderate to severe left ventricular impairment | Requires adequate monitoring and maintenance of normovolaemia to prevent haemodynamic instability and possible myocardial ischaemia in susceptible patients | This is a widely available, low cost option with the potential advantage of a reduction in blood viscosity. Efficacy in reducing transfusion requirements has been questioned |
| Preop component collection (e.g. platelet-rich plasma) | | | | Research technique. Controlled studies have so far failed to confirm efficacy |
| Red cell salvage centrifugal processors | Elective and emergency surgery with expected loss >20% TBV | Bacterial contamination of wound; malignant disease; sickle cell disease and sickle cell trait are relative contraindications | In large volume losses risk of dilutional coagulopathy. Preventable with component Rx.<br>Training required for operator | Excellent long-standing safety record. Becomes increasingly cost effective with large volume losses. Some Jehovah's Witnesses will accept this. |
| Red cell salvage haemofiltration processors | As above | As above | Relatively new technology. Training required for operator. | Slower processing than centrifugal devices. Filter needs changing after 2 processing cycles |
| Red cell salvage single reinfusion devices | As above | As above | Safety and efficacy to be demonstrated by larger studies.<br>Worries concerning reinfusion of activated clotting factors, may increase risk of DIC | Simple and cheap for low volume losses |
| Red cell salvage mediastinal reinfusion | Postop. cardiac surgical patients emergency/elective | Sickle cell disease, bacterial contamination of wound | Worries concerning reinfusion of activated clotting factors, may increase risk of DIC | Unprocessed defibrinated blood transfused. Reduces banked blood requirements in patients with high mediastinal losses |

# CORRESPONDENCE

## Use of rocuronium in a pregnant patient receiving magnesium medication

Sir,—The report by Gaiser and Seem[1] highlighted some important aspects of the use of non-depolarizing neuromuscular blocking agents in the presence of magnesium infusions. In their patient, the use of rocuronium for neuromuscular block was followed by prolonged paralysis. However, there are several problems with this report. The dose of rocuronium used was well in excess of the usual recommended dose of 0.6 mg $kg^{-1}$. The prolongation of non-depolarizing neuromuscular block by magnesium is so well known that the decision to use such a high dose of a non-depolarizing blocker needed to be very carefully considered. If it was known at the outset that the case was to last 6 h, then the use of rocuronium in these circumstances is acceptable, but prolongation of its action should have been expected. The validity of the choice of blocker is also open to debate. The evidence against the use of suxamethonium in patients with open eye injuries is, at best, weak. There is little hard evidence that the small increase in intraocular pressure (IOP) seen after the use of suxamethonium poses a real threat to the injured eye and several strategies are available to limit this increase in IOP.[2] In addition, magnesium decreases the fasciculations produced by suxamethonium,[3] and is likely to limit the increase in IOP consequent on suxamethonium use. The aspiration risk in this patient was clear, and it seems inappropriate to consider the minute risk of ocular injury from suxamethonium ahead of the hazards associated with the use of a non-depolarizing neuromuscular blocking agent.

The plasma concentrations of magnesium referred to in this case report must be wrong. I suspect that the units were erroneously quoted as mmol $litre^{-1}$ whereas the reported values are consistent with mEq $litre^{-1}$. It is extremely unlikely that, at the doses of magnesium given, the concentration in plasma would have been 5.8 mmol $litre^{-1}$. The correct therapeutic range is not 4–8 mmol $litre^{-1}$ as quoted in this article, but 2–4 mmol $litre^{-1}$. The quoted values tally with the normally quoted mEq $litre^{-1}$ range, those for molar concentrations being half the concentration reported when equivalents are used for divalent ions.

The important lesson of this report is that the well known interactions of magnesium and neuromuscular blocking agents should always be borne in mind. Careful selection of appropriate drugs and dosage is vital if this type of complication is to be avoided.

3. Stacey MR, Barclay K, Asai T, Vaughan RS. Effects of magnesium sulphate on suxamethonium-induced complications during rapid-sequence induction of anaesthesia. *Anaesthesia* 1995; 50: 933–936.

Sir,—We appreciate the comments of James on our case report, especially those concerning the units for the plasma concentration of magnesium. In the original manuscript, it was mEq $litre^{-1}$. We apologize for the error in typesetting.

However, we disagree with several of his other statements. After initiating the case, we knew the neuromuscular blocking effects of rocuronium would be prolonged by magnesium; it was the extent with which we were unsure. In determining the risk and benefit of using rocuronium, we felt the benefit of avoiding the increase in intraocular pressure (IOP) outweighed the risk of possible postoperative intubation and ventilation should surgery conclude before its action had terminated.

He also states that the dose of rocuronium, 0.9 mg $kg^{-1}$ ($3 \times ED_{95}$), was excessive. As outlined in the manuscript, this dose, compared with 0.6 mg $kg^{-1}$, decreases the onset time to complete neuromuscular block by 50%.[1] In the pregnant patient who is prone to oxygen desaturation on induction, we felt that rapid securing of the airway to be most important.[2] As such, the higher dose was used.

Suxamethonium increases IOP by approximately 8 mm Hg. James stated that magnesium may attenuate this increase as magnesium would decrease the fasciculations produced by suxamethonium. Contraction of the extraocular muscles does not completely account for the increase in IOP. Pretreatment with a non-depolarizing neuromuscular blocking agent to prevent fasciculations does not reliably prevent this increase.[3] In fact, in patients scheduled for elective enucleation who had all of the extraocular muscles detached, suxamethonium still increased IOP.[4] Therefore, one would have to question if magnesium would limit the increase in IOP by suxamethonium.

Finally, James suggests the use of propofol and alfentanil to attenuate the increase in IOP. Although these agents may be helpful, it is important to remember that the patient was a 31-yr-old parturient with a 28-week gestation. Although propofol has been used successfully during pregnancy, it is not recommended.[5] There are no adequate and well-controlled studies concerning the use of alfentanil during pregnancy. Its use as a continuous extradural infusion during labour has been investigated. Neonatal hypotonia was observed.[6]

## Hepatocellular integrity after inhalation anaesthesia

Sir,—In their study of hepatocellular integrity after inhalation anaesthesia, Tiainen and Rosenberg[1] found that GSTA concentrations increased in patients who received isoflurane or halothane, but the increase appeared greater in those receiving halothane. As they point out, this contrasts with previously published studies,[2 3] and they speculated on possible reasons for this. We believe the discrepancy between their findings and ours is explained by the use of different modes of ventilation in the two studies, and not from differences in the concentrations of agents administered.

There is little doubt that GST concentration measured by specific radioimmunoassay does not increase in normotensive, spontaneously breathing patients who receive isoflurane. Of the 18 patients who received isoflurane, only two showed an increase in GST concentration (4.1 and 4.3 μg $litre^{-1}$) after anaesthesia.[2] This confirmed results from a previous study in which no patient who received isoflurane showed an increase in GST concentration after anaesthesia.[4] In contrast, we have shown that the mode of ventilation significantly influences GST concentration more profoundly than the use of different volatile anaesthetic agents.[5] We studied 48 patients undergoing controlled hypotension for middle ear surgery who were allocated to one of four groups to receive either IPPV or SV, and halothane or isoflurane. GST concentrations increased at 1–3 h after the end of anaesthesia in all four groups but there was no significant difference in GST concentration between patients who had received halothane or isoflurane, irrespective of the mode of ventilation. Combining the results obtained using the two volatile agents allowed assessment of the effect of ventilatory mode and revealed that GST concentration was significantly greater at 1 h after the end of anaesthesia in patients who had received IPPV (pre-induction 2.3 μg litre$^{-1}$; 1 h 3.6 μg litre$^{-1}$) than in those who had breathed spontaneously (pre-induction 2.5 μg litre$^{-1}$, 1 h 2.6 μg litre$^{-1}$).

We do not consider that differences in concentration of volatile agents administered account for the differences observed between the study of Tiainen and Rosenberg and ours. We have never found that the change in GST from preoperative values is related to dose of anaesthetic agent or to duration of anaesthesia.

Murray, Rowlands and Trinick did not find any increase in GST concentration after isoflurane anaesthesia in patients who received IPPV.[3] We agree with Tiainen and Rosenberg that the likely reasons for this include the relatively insensitive GST assay used and infrequent sampling after anaesthesia. It should also be noted that whereas Murray and Tiainen's groups measured total alpha class GST (i.e. $B_1$ and $B_2$ subunits), we measured only GST $B_1$ subunits in our studies; measurement of $B_1$ subunits appears more sensitive than $B_2$ at detecting hepatic damage.

We believe that hepatocellular integrity is not impaired in spontaneously breathing patients who receive isoflurane, and that mode of ventilation has a greater influence on GST concentration after anaesthesia than the use of different inhalation anaesthetic agents.

Sir,—Thank your for the opportunity to respond to the comments by Ray, Beckett and Allan concerning our study on hepatocellular integrity after isoflurane and halothane anaesthesia.[1] The two differences between our study[1] and that by Hussey and co-workers[2] were: (1) in our study there was no significant difference in GSTA between the isoflurane and halothane groups; and (2) in our study GSTA increased also in the isoflurane group. The latter fact may, indeed, have been caused by the influence of positive pressure ventilation in normotensive patients as seems to be the case in patients operated on under deliberate hypotension.[3] However, the former requires other explanations.

For about 9 yr it has been thought that halothane anaesthesia is usually associated with a disturbance in hepatocellular integrity while isoflurane anaesthesia is not.[2] Our study challenged this "truth".[1] We cannot totally reject our speculation that the former difference between the studies is caused by previous exposure to halothane or by differences in concentration of anaesthetics Halothane was probably more commonly used in Scotland in the 1980s than in Finland in the 1990s. The change in GSTA seems not to be related to the dose of anaesthetic agent or to duration of anaesthesia, but we have not found any study on GSTA comparing different concentrations of volatile anaesthetics, or comparing different durations of anaesthesia to prove these concepts Murray, Rowlands and Trinick[4] used a relatively insensitive assay and found a difference in GSTA concentration between halothane and isoflurane at 2 MAC for 10 h. There was also an increase in aspartate aminotransferase.[4] On the other hand, we found no significant difference between these anaesthetics at 1 MAC for 3 h.[1] In the studies in which Ray, Beckett and Allan have been co-authors,[2 3] the concentrations of volatile anaesthetics and the changes in GSTA concentration seemed to fall between these extremes.

We agree that positive pressure ventilation may be an important cause for the increase in GSTA after isoflurane anaesthesia but we need other explanations for the lack of difference between isoflurane and halothane. The increase in GSTA concentration after sevoflurane anaesthesia is also interesting because it occurs after positive pressure ventilation[5] but also after spontaneous ventilation.[6]

## Safety issues and volatile agent analysers

Sir,—Drs Strachan and Richmond raised some interesting points in their case report concerning the presence of diethyl ether in an isoflurane vaporizer.[1]

Older Datex anaesthetic agent monitors are calibrated to measure levels of halothane, enflurane, isoflurane and methoxyflurane. It has been noticed in this hospital that when using sevoflurane the agent monitor seems to give readings corresponding to the vaporizer settings when set to measure methoxyflurane which is not seen when the agent monitor is set for any other volatile agent. This was purely a chance observation and has certainly not been used clinically as a monitoring method.

It does however seem surprising, given the different physical and chemical properties of sevoflurane (molecular weight 200.1, blood:gas partition coefficient 0.69, boiling point 58.6°C) and methoxyflurane (molecular weight 165, blood:gas partition coefficient 13, boiling point 105°C) and the seemingly closer similarity of sevoflurane to the routinely used volatile agents.[2] This must reflect similar infrared absorption bands of sevoflurane and methoxyflurane.

This would seem to indicate that in some circumstances two compounds with quite distinct properties can effect monitoring in similar ways given similar absorption spectra. This shows that advancing the scope of anaesthesia in one area must be paralleled by the ability to use appropriate monitoring techniques and, at best, monitoring is only an adjunct to clinical vigilance.

## Ether in an isoflurane vaporizer and the use of vapour analysers in safe anaesthesia

Sir,—We read with interest the case report by Strachan and Richmond[1] and wish to make the following comments.

The ether-filled temperature compensation unit used in the PPV Sigma has been used safely in Penlon vaporizers for more than 40 yr and was one of the world's first automatic TC units, having been first introduced into the EMO vaporizer.

The design of the now obsolete PPV Sigma vaporizer discussed in the article necessitated a significant TC movement that was not possible to obtain by bimetallic expansion alone. That movement could only be provided by that type of liquid-filled expansion system.

The current range of Penlon Elite vaporizers makes use of significantly different control variables and as a result of these major design changes Penlon vaporizers no longer use liquid-filled TC units but do use a solid state bimetallic TC unit in common with some other manufacturers.

## Non-invasive measurement of cerebral blood flow

Sir,—I read with interest the recent article by Gupta and co-workers.[1] It was only when I set out to derive the equations presented within this article that I realized that one of the definitions is wrong. The authors define CLVHR as "the coefficient of the large to small vessel packed cell ratio" whereas it is the inverse, the ratio of cerebral (small vessel) to large vessel haematocrits, as derived by Lammertsma and colleagues[2] and calculated as 0.69. It is the definition that is misleading, the equations are correct for the value quoted. Unfortunately, Gupta and co-workers have simply compounded the original error in definition given by Elwell and co-workers.[3]

My second comment is on the use of $F\mathrm{E}'_{CO_2}$ as equivalent to $Pa_{CO_2}$ when calculating carbon dioxide reactivity. First, the normal value for $Pa_{CO_2}$ is 5.3 kPa but this does not equate to an $F\mathrm{E}'_{CO_2}$ of 5.3 kPa. At rest, with quiet respiration, there is a small difference of 0.3–0.6 kPa between $Pa_{CO_2}$ and $F\mathrm{E}'_{CO_2}$. Thus data should have been indexed to a normal value for $F\mathrm{E}'_{CO_2}$, namely 4.85 kPa. The difference between $Pa_{CO2}$ and $F\mathrm{E}'_{CO_2}$ is important in the context of this study as respiration is altered to achieve different $F\mathrm{E}'_{CO_2}$ values. We are not told how the volunteers hyperventilated to reach a $Pa_{CO_2}$ of 3.5 kPa, but most people would increase ventilatory frequency and tidal volume may decrease; conversely, adding carbon dioxide to the gas mixture triggers hyperventilation largely by increasing depth of ventilation in addition to ventilatory frequency. As the difference between $Pa_{CO_2}$ and $F\mathrm{E}'_{CO_2}$ is dependent on tidal volume, the slope of the CBV *vs* $F\mathrm{E}'_{CO_2}$ line is no longer identical to the slope of the CBV *vs* $Pa_{CO_2}$ relationship. Physiologically, carbon dioxide reactivity is dependent on $Pa_{CO_2}$ not $F\mathrm{E}'_{CO_2}$ and so this source of error in determining carbon dioxide reactivity should be discussed as we are not told if the volunteers were asked to maintain a constant tidal volume for all parts of the study.

The lack of any significant change in packed cell volume in relation to $F\mathrm{E}'_{CO_2}$ is indeed puzzling when the calculated values for CBV are clearly related to $F\mathrm{E}'_{CO_2}$. Although the possibility of following changes in CBV non-invasively may be useful clinically, particularly for head injuries, to do this by altering $Pa_{CO_2}$ is not acceptable. It seems this point must be addressed before the methodology presented here is acceptable.

Sir,—I read with interest the article by Gupta and colleague[1], but have grave doubts on the validity of the conclusions regarding the ability to non-invasively assess cerebral blood volume, for several reasons.

First, no currently available near-infrared (NIR) spectroscopic system has the ability to completely exclude the scalp signal, which may potentially cause a great deal of artefact Second, the oxidized and reduced haemoglobin concentrations were derived from NIR absorption spectra by an algorithm, introducing a further potential inaccuracy. Third, calculation of $[Hb_{calc}]$ involves examining the changes in the derived signals, thereby compounding the error of an algorithm with the influence of the scalp tissue signal. Possibly this helps explain the 25% difference in the calculated cerebral blood volume (CBV) reactivities of 1.25 and 1.06 ml 100 $g^{-1}$ $kPa^{-1}$ when $HbO_2$ or $Hb_{diff}$ concentrations were used to perform the calculation. Fourth, CBV calculated in ml 100 $g^{-1}$ assumed a large number of variables to be constant. Haemoglobin was assumed to be 15 g $dl^{-1}$, even though five of 13 subjects were female and of an age likely to be menstruating. The coefficient of large to small vessel packed red cell ratio is assumed to be constant throughout, even though the authors noted that flow, as measured by transcranial Doppler, changed with moderate differences in oxygen content indicating vasoreactivity, which must surely change the large to small ratio.

Lastly, there is no "gold standard" with which the authors have compared their results, and although they may have measured changes in cerebral blood volume, one cannot be sure from this study.

1. Gupta AK, Menon DK, Czosnyka M, Smielewski P, Kirkpatrick PJ, Jones JG. Non-invasive measurement of cerebral blood volume in volunteers. *British Journal of Anaesthesia* 1997; 78: 39–43.

Sir,—We thank Drs Hill and Williams for their comments.

In response to Dr Hill, we agree that the definition of CLVHR is the small to large vessel haematocrit ratio, as described by Lammertsma and colleagues.[1]

The study aimed to evaluate non-invasive methods of assessing cerebral blood volume. While we accept that there is a small difference in $Pa_{CO_2}$ and end-tidal carbon dioxide ($F\mathrm{E}'_{CO_2}$), arterial blood-gas monitoring was not used as described in the article. The data were indexed to the calculated CBV at an $F\mathrm{E}'_{CO_2}$ of 5.3 kPa. Although this does not equate to a $Pa_{CO_2}$ of 5.3 kPa, the regression equation of CBV reactivity should not be affected.

Further, the expression of CBV reactivity as a percentage of baseline CBV compensates for individual variations in baseline CBV. End-tidal carbon dioxide manipulation is a recognized method of measuring carbon dioxide reactivity[2] and is used clinically to assess carbon dioxide reactivity. However, we would not alter $Pa_{CO_2}$ to measure CBV in head injured patients. This is not implied in the study; we have used $Pa_{CO_2}$ variations in volunteers merely as a paradigm of CBV alterations in volunteers and these changes would result from spontaneous pathophysiological mechanisms in disease.

In response to Williams' comments, it is well recognized that there is extracranial contamination in the near infrared signal. It has been reported that there is approximately a 15% contribution of skin changes to the $HbO_2$ signal during carbon dioxide challenge, and much of this change is related to changes in systemic arterial pressure.[2] Our volunteers showed no significant change in MAP. It therefore seems unlikely that changes in skin blood flow contributed significantly to the carbon dioxide reactivity of the NIR signal. The use of an estimated Hb value and the approximations involved in the calculation may have biased the absolute level of CBV measured, but are unlikely to have affected reactivities.

While there is as yet no direct comparison of NIR measurement of CBV and CBV reactivity against the gold standard of positron emission tomography (PET), we have discussed our results in the context of data obtained by other authors and different techniques, including PET.[3]

## Tolerance of laparoscopy for resection of phaeochromocytoma

Sir,—In their report of two cases of intraperitoneal laparoscopic phaeochromocytoma resection, Mann and colleagues suggested that haemodynamic disturbance associated with pneumoperitoneum in one case may question the safety of this approach.[1] Such a conclusion cannot be justified on their evidence in which adequate preoperative preparation was given such a low priority.

They stated that 10 days preoperative treatment failed to provide satisfactory haemodynamic control in a patient, yet despite this, surgery was allowed to proceed. They then claimed that the hypertensive response to peritoneal insufflation in this patient reflected a risk associated with pneumoperitoneum rather than inadequate preoperative preparation. Notably, the second case (in which arterial pressure was stabilized before surgery with 20 days' treatment) showed no vasopressor response to pneumoperitoneum.

While no controlled, randomized study has been performed, it is generally agreed that preoperative preparation is the major factor in the reduction in perioperative morbidity and mortality and indeed preoperative therapy is mandatory in patients with sustained or paroxysmal hypertension.[2]

Their choice of antihypertensive drugs is also worthy of comment. They used nicardipine and, in the first case, labetolol. Calcium channel blockers such as nicardipine have been used in the perioperative period but cannot be regarded as "agents of choice" on the references quoted.[3 4] Labetolol is inadequate to control arterial pressure if large quantities of noradrenaline are released[5] and has been reported to cause paradoxical hypertension in patients with phaeochromocytoma[6] because of its potency at β relative to α receptors. Labetolol is therefore regarded as a poor choice of drug in the management of patients with phaeochromocytoma.

α-Adrenergic blockade, restoration of plasma circulating volume and β-blockade if required to control tachyarrhythmias are widely accepted for preoperative preparation.

Mann and colleagues refer to the retroperitoneal approach and apparent cardiostability of such cases, as reported by Giebler and colleagues.[7] It is worth noting that these patients were treated with phenoxybenzamine for 21 days before operation.

Sir,—We thank Drs Jerwood and Willis for their interest in our investigation[1] but their letter deserves comment on two points: first, preoperative preparation, and second, effect of pneumoperitoneum.

We agree that no controlled, randomized study has demonstrated that preoperative preparation for phaeochromocytoma reduces perioperative morbidity and mortality. It is also not established that preoperative treatment should last at least 21 days to improve perioperative haemodynamic stability. Moreover, no preoperative preparation can control all perioperative haemodynamic events.[2] The issue of the need for any preoperative preparation has even been questioned elsewhere.[3] α-Adrenergic blockade requires time to be fully effective (this sometimes "justifies" up to 21 days of preparation!) and has many drawbacks: (a) arterial pressure instability when inducing treatment may delay the time of completing vasodilator therapy, (b) decreased venous tone and cardiac preload, and (c) increased risk of severe postoperative hypotension, especially with long-acting drugs such as phenoxybenzamine. In our experience, dihydropyridines allow short-term preoperative preparation,[4] do not induce arterial pressure instability, do not adversely affect venous return and cardiac preload, and do not cause severe postoperative hypotension. All of these features provide many reasons to choose dihydropyridines rather than α-adrenergic blocking drugs for preoperative preparation of phaeochromocytoma surgery.

Labetolol was used as a β-blocking drug, and it was added to a preliminary vasodilator therapy; therefore the risk of paradoxical hypertension was avoided.

In the first of the two case reports, peritoneal insufflation induced a severe increase in catecholamine concentration that mimicked adrenal tumour response to surgical manipulation. This is the evidence that insufflation of the pneumoperitoneum may induce direct stimulation of the adrenal tumour. Even 21 days of phenoxybenzamine preparation would not have avoided this catecholamine release from the adrenal tumour, as α-adrenergic blockade does not act on tumour secretion. Therefore, our conclusion is justified and we recommend caution with peritoneal insufflation for laparoscopic phaeochromocytoma resection.

## Airway problems after carotid endarterectomy

Sir,—I read with interest the article by Munro, Makin and Read[1] describing four cases of acute respiratory obstruction after development of postoperative wound haematomas following carotid endarterectomy. They make the point that such patients require continuous respiratory monitoring in order to detect developing respiratory obstruction at an early stage. It is worth emphasizing that the neurological complications they refer to after carotid endarterectomy may include changes in respiratory function and control.[2] The presence of hypoventilation or even apnoea[3] would make the obstructive effect of postoperative haematoma even more rapid in onset. Gradual onset of respiratory obstruction may also lead to hypercapnia, which by means of the development of cerebral steal syndromes might lead to a decrease in blood flow in already ischaemic areas of the brain, thereby exacerbating the already compromised control of respiration. Inadequate control of arterial pressure in the postoperative period increases this effect in addition to increasing the size of postoperative wound haematomas.

## *In vivo* and *in vitro* dose–response curves

Sir,—Our Japanese colleagues[1] have made a good attempt in interpreting human anaesthetic dose–response curves at a molecular level. But they admit that not all the values they have derived are plausible. May I offer two suggestions?

They used the method of least squares, however, this has underlying assumptions that the data are Gaussian and homoscedastic, neither of which is true for quantal data. One method of analysing quantal data was described by Waud[2]: the appendix provides a simple BASIC program, which will solve equation (2) of the Osaka study. Waud's programme is translated easily into Microsoft Professional Basic, a language which overcomes most of the objections to old BASIC raised by computer professionals.

Second, the Osaka team suggested that the *in vivo* curve is the outcome of a normal, or log-normal, array of events at the molecular level. If so then their equation (2) would match reality better as a series, not a single unit:

$$y=\frac{x^{n_1}}{K_1{}^{n_1}+x^{n_1}}+\frac{x^{n_2}}{K_1{}^{n_2}+x^{n_2}}+\ldots$$

Adding one unit should reduce residual variance and the experiment repeated until there is no further improvement. With three units the solution would require inverting a 6×6 matrix, but that is no problem in Professional Basic, which has an efficient algorithm for any size of matrix.

Lastly, anaesthetics act on the synapse; if 1% halothane reduces transmission across each synapse to 70% of normal, then over a relay of five synapses it is decreased to 17% (0.7$^5$). Does it not follow that the *in vivo* curve should be steeper than effects at single synapses? This is why a simple reflex, such as withdrawing the foot, can be present when consciousness has been extinguished, as John Snow noticed 150 yr ago. May I wish them good luck with their endeavours.

2. Waud DR. On biological assays involving quantal responses. *Journal of Pharmacology and Experimental Therapeutics* 1972; **183**: 577–607.

Sir,—We appreciate the letter of Dr Cormack which relates to our article on dose–response curves.[1] He suggests that assays of *in vivo* dose–response data have to be treated by the method of analysing quantal data, instead of the method of least squares, as described by Waud.[2] According to Waud's programme, we have re-examined the *in vivo* data and obtained revised results as follows: ED$_{50}$=1.01%atm (SEM=0.08%atm), $n$=3.59 (SEM=0.89) for isoflurane, and ED$_{50}$=0.76%atm (SEM=0.008%atm), $n$=29.2 (SEM=7.6) for halothane. These results are in agreement with those in our articles (ED$_{50}$=1.03%atm, $n$=3.6 for isoflurane; ED$_{50}$=0.75%atm, $n$=27 for halothane). Therefore, our least square fittings did not differ markedly from quantal assays.

Second, he suggests better fitting of data to the Hill equation (2) in our text by adding another unit. This may be effective for reducing residual variance, but the biological or molecular meaning of the adding term is not clear. Such a modification should be plausible when two or more doses are applied simultaneously,[2] or when some integrated effects take place on an organism, such as linkage effects between two or more receptor molecules each of which can bind with a drug molecule. In both cases, however, we have another problem, whether or not simple addition of one unit is suitable, because it depends on an adopted model.

Lastly, he mentioned an effect of a series of synapses. This is an interesting suggestion, but if there were a long series of synapses, only a small amount of dose applied would anaesthetize any patient. In other words, it cannot show the existence of a critical dose value above which a patient does not respond; the critical value is different between patients. In a complicated system of neurone networks, information propagates backwards in addition to forwards, and then some integrated response emerges. We suggest that this must be responsible for the existence of the critical dose value mentioned above. Although our MWC model oversimplifies the system, the model inherently has an integrated nature.

We thank Dr Cormack for his valuable suggestions and his interest in our article.

## Ambulatory extradural analgesia in labour and mode of delivery

Sir,—Drs May and Elton[1] recently reported the results of a small prospective study comparing standard non-ambulatory extradural analgesia (boluses of 0.25% bupivacaine 10 ml) with ambulatory combined spinal–extradural analgesia (spinal bupivacaine 2.5 mg and fentanyl 25 μg followed by extradural top-ups of 0.1% bupivacaine 10 ml with fentanyl 2 μg ml$^{-1}$). They found that the rate of emergency Caesarean section was significantly lower in the ambulatory group (three of 30 *vs* 11 of 37; chi-square=3.89, $P$<0.05). If valid, this finding would be a major step forward for obstetric anaesthesia.

The first ambulatory, or mobile, extradural at the Royal Surrey

County Hospital was performed in late 1993. Because of the high rate (2.3%) of post-dural puncture headache after combined spinal–extradural analgesia reported by Collis and colleagues,[2] we adopted successfully a technique using extradural boluses of 0.1% bupivacaine 20 ml with fentanyl 2 $\mu$g ml$^{-1}$, without a spinal and without a conventional test dose. In 1996, 1100 (95.8%) of the 1148 extradurals (42.4% of labouring mothers) given for pain relief used this mobile technique, compared with one (0.11%) of 907 extradurals (35.2% of labouring mothers) in 1993.

Unfortunately, there has not been a reduction in the rate of emergency Caesarean section in mothers using extradural analgesia. In 1993, 78 (8.6%) of 907 mothers with extradurals required emergency Caesarean section compared with 146 (12.7%) of 1148 in 1996. This is a statistically significant increase (chi-square=8.8, $P<0.01$). However, there has also been a significant increase in the number of mothers having a spontaneous vaginal delivery, from 432 (47.6%) in 1993 to 646 (56.3%) in 1996 (chi-square=15.9, $P<0.001$) and a significant decrease in the number of instrumental deliveries, from 397 (43.8%) in 1993 to 356 (31.0%) in 1996 (chi-square=35.5, $P<0.001$). In those mothers who did not receive an extradural, the rates of spontaneous vaginal delivery, instrumental delivery and emergency Caesarean section have not changed significantly between 1993 (85.4%, 5.3% and 9.3%, respectively) and 1996 (87.8%, 4.2% and 8.0%, respectively). A randomized study by Collis, Davies and Aveling[3] comparing ambulatory combined spinal–extradural analgesia with standard non-ambulatory extradural analgesia found no difference in the outcome of labour. However, Asselineau[4] observed a significantly lower instrumental delivery rate but similar Caesarean section rates in the ambulant group when comparing ambulant and non-ambulant extradurals. Experience at this hospital suggests that the use of mobile, or ambulatory, extradurals may lead to a higher rate of spontaneous vaginal delivery and a lower rate of instrumental delivery.

Sir,—We thank Dr Jenkins for his interest in our small randomized study[1] comparing extradural analgesia using 0.25% bupivacaine with a previously described combined spinal–extradural (CSE).[2] His large retrospective audit of extradural technique and mode of delivery confirmed the findings of some,[3 4] although not all, studies.[5 6] We appreciate his anxiety about the use of the subarachnoid component of this technique with regard to reports of meningitis after CSE in labour.[7] The evidence for an increased incidence of post-dural puncture headache is however not so clear.[8] It is possible that the ability to provide pain-free ambulation in labour may be beneficial if it is produced using an extradural only technique or a CSE. We have recently commenced a much larger collaborative study with colleagues at Birmingham Women's Hospital comparing these techniques and we hope this will demonstrate if the spinal component of a combined spinal–extradural is essential for the beneficial effect suggested in our study.

## The "Dumfries claim"

Sir,—The reference to the first trial of ether anaesthesia at Dumfries and Galloway Royal Infirmary on 19 December 1846 (in your editorial[1]) is dismissive and, as such, deserving of comment. In an allusion to William Scott's assertion of priority over Robert Liston with regard to the date, Professor Spence refers to the "Dumfries claim", quoting, I presume, the title of my original paper in your journal.[2]

The "claim", as Professor Spence correctly stated, was contained in William Scott's letter to *The Lancet*[3] on October 19, 1872, one of the no fewer than three reliable references to the validity of Scott's assertion. While the question of precedence was an important personal issue for William Scott, at no time did he infer that his early application of anaesthesia at Dumfries had any influence on the rapid acceptance of ether. Nevertheless, had James Y. Simpson been in Edinburgh at the time, in which case the news of Scott's operation would have reached him almost immediately, the Old World would doubtless have been informed of the anaesthetic properties of ether through alternative channels! In that case, Robert Liston might well have had to share the honours with his colleagues in south-west Scotland.

The suggestion by Professor Spence that James Y. Simpson travelled to London "for the specific purpose of learning about anaesthesia" would appear to be incorrect. Simpson's journey to London in December 1846 was the first of two visits in connection with his appointment as surgeon to Her Majesty Queen Victoria's household in Scotland and, on the date of the Squire:Liston success, he was either on his way to, or had already arrived in, London. He received the news of ether, therefore, not from London but in London.

The narrative surrounding the Dumfries operation is a fascinating one and has been the subject of several publications by this writer over the past 30 yr.[4 5] The gentlemen at Dumfries provided the chronicles of anaesthesia with a remarkable story and the fact that particulars regarding the patient are, as yet, incomplete does not lend the right to dismiss the incident with, "the outcome, whatever it was, adds nothing to science or medicine".

Sir,—Writing from this address about the arrival of ether anaesthesia in Britain, what is one to do? Having mentioned Dumfries, thus hoping to avoid the letters that would have been sent had I failed to do so, it was necessary to give a brief evaluation of the significance of the event.

I am grateful to Dr Baillie for drawing attention to the revised account of Simpson's movements around Christmas, 1846. Dr Baillie will understand that I did not have the benefit of his interesting 1996 book[1] until after the editorial had been published. As it happens I had been guided by the sentence "no sooner had word of the first successful demonstration of surgical anaesthesia in London reached the Scottish capital than Simpson was on his way south." This is taken from Dr Baillie's 1966 book.[2] Even if Simpson had remained in Edinburgh in the relevant days, it is difficult to know how he might have been the vehicle through whom the Old World would have heard the news The problem of the "Dumfries claim" is one of non-communication. Simpson was just as much in the dark as everyone else

## Allergies and anaesthesia

In their case report,[1] Rae, Milne and Wildsmith highlighted the importance of obtaining a detailed history, particularly in the area of allergies. I recall a similar case also during a Caesarean section under regional anaesthesia which reinforces this point.

A 35-yr-old ex-nurse, with atopy but no known allergies, underwent a routine combined extradural–spinal anaesthetic for elective Caesarean section. Catheterization with a latex urinary catheter was uneventful. Just after delivery and a bolus of i.v. oxytocin she complained of "feeling unwell' and said her tongue "felt swollen", she developed an erythematous rash on her upper body with visible facial oedema and her arterial pressure rapidly became unrecordable. A diagnosis of anaphylaxis was made; amniotic fluid embolus was part of the differential diagnosis. Treatment with oxygen, i.v. crystalloid and adrenaline rapidly restored her to her previous state. A similar, but less severe, episode occurred before surgery was completed. Recovery was uneventful, the urinary catheter was removed 24 h after operation.

It was only afterwards on direct questioning that the patient described past episodes of facial swelling on blowing up balloons, contact dermatitis to rubber gloves and vaginal irritation to condoms. Skin prick testing proved highly positive for latex, and negative for oxytocin, bupivacaine and Gelofusine.

This case also demonstrates that the risk of latex allergy in medical staff (2.8%) is greater than that found in patients presenting for skin prick tests (0.8%) although theatre staff are at greatest risk (7.8%).[2] Repeated latex exposure is believed to be responsible for these observations.

Latex-containing products release variable amounts of antigen (water-soluble proteins), examination gloves and urinary catheters releasing far more than surgical gloves. This may explain why anaphylactic reactions associated with the former commonly occur within 2–3 min, as in Rae, Milne and Wildsmith's case, while those associated with surgical gloves contacting the large absorptive surface of the abdomen (the commonest reported route) often take longer to develop, typically 40–300 min,[3] as in the above case. Why the two patients reacted so differently I am at a loss to explain.

Since the original case report[4] latex sensitivity has become recognized as a relatively common cause of allergic dermatitis and anaphylaxis. This may be caused by a combination of change in the manufacturing process, greater antigen exposure, heightened clinical awareness and more frequent use of latex as an antigen during investigations of drug reactions. Whatever the cause it is necessary to inquire about latex sensitivity from all of our patients to avoid similar scenarios.

# BOOK REVIEWS

*Airway Management.* L. H. HANOWELL AND R. J. WALDRON (eds). Published by Lippincott-Raven, Philadelphia. Pp. 480; indexed; illustrated Price £73.00.

This is a new text with contributions from authors based mainly in California, Texas, Alberta and various parts of Australia. Many of the chapters are multi-authored and the general effect of this appears to be to increase the effectiveness rather than cramp the style There is a clear attempt to provide an authoritative review rather than a simple listing of the large number of relevant references. A UK reader will be interested in the meat of the text and find the relatively standard pharmaceutical contributions (i.e a chapter each on i.v. anaesthetics, inhalation anaesthetic agents, neuromuscular block and opioids) out of place, especially as there is little direct application specific to the main thrust of the text.

The description of algorithms and "what to do next" was handled sympathetically and advice generally constructive, presumably reflecting the multi-authorship. The practical descriptions of the less common techniques were detailed clearly with appropriate illustrations. There was extensive cover of most of the specialist clinical areas associated with difficult airway My personal view is that in many of these areas the anaesthetist tends to take more of a leading role than in most other clinical situations and needs not only to be diagnostically aware but also able to determine imaging requirements appropriate to the anaesthetic rather than just surgical needs. This needs to be reflected more clearly when describing acute airway events in major ENT and faciomaxillary surgery.

It is particularly surprising, especially in view of the title of the book, that so little space is devoted to the many problems posed by sleep apnoea and its medical and surgical management. This is especially surprising when there is a whole chapter on routine medical considerations for lower airway obstruction caused by asthma Although relatively short, there is a thought provoking chapter on blunt trauma and the major airways and the important diagnostic and management difficulties that may be encountered in these patients. Overall the chapter on cervical spine injury is fairly balanced but there is a section devoted to advice on ATLS nasal intubation in some detail, that ends with a cautionary tale. This is followed immediately by advice about fibreoptic intubation. Although it is stated that a difference between elective and emergency cases is important there is also an implication that the answer is "skilled hands and proper patient selection".

Overall I found parts of this textbook informative and interesting. I doubt that many anaesthetists in the UK would want to purchase it for their own personal use because of what will be seen as redundant material which is dealt with better in other standard anaesthetic texts. It would be easy to recommend it for purchase by postgraduate medical libraries because of the extensive coverage of less common techniques. At the same time, however, there are several other texts available at present and whether or not this holds a place against the competition in the longer term remains to be seen.

*P Charters*

*Essentials of Anesthesiology*, 3rd Edn D. C. CHUNG AND A M. LAM. Published by WB Saunders, Philadelphia. Pp. 351; indexed; illustrated. Price £22 95.

This text is intended to be a pocket book for the trainee doctor in anaesthesia and aims to provide basic knowledge of general anaesthesia. The authors accept that the text is not comprehensive and subspecialties are not covered. The range of topics covered is comprehensive and up to date with particularly good chapters on blood transfusion, quality assurance and risk management, and airway management.

This book is designed to complement the lectures, tutorials and theatre teaching which the beginners receive in the first 3 months. It therefore fulfils this objective by the use of short, clear sections with an adequate number of diagrams, tables and illustrations.

This book is very enjoyable to read. It is not a book which will benefit examination candidates. Its English is simple, the diagrams are very illustrative and clear and I would recommend it to those who are beginners in anaesthesia.

Although based on American practice, this does not detract from the value of the book for a trainee working in anaesthesia anywhere in the world. It certainly represents good value for money.

*I Jeyapalan*

*The Adult Spine, Principles and Practice*, 2nd Edn. J. W. FRYMOYER (ed). Published by Lippincott-Raven, Philadelphia. Pp 2443; indexed; illustrated. Price £257.00.

These two volumes constitute as complete a text as a spinal surgeon could wish to have. The specialty of spinal disorders has grown enormously in recent years. Afflictions of the axial skeleton overlap and impact on most specialties within medicine and this text should be available in all quality medical libraries.

Pain management specialists would be particularly interested in the chronic pain chapters. The overall approach is evidence-based but individual authors give their own perspective on treatment modalities. The history, epidemiology and economics sections give the reader an insight into how we have arrived at the present epidemic of back pain. Chapters on functional restoration and pain management programmes are by world authorities and the handy hints contained within could well enhance the limited and oversubscribed services of this nature in the UK. There is a wealth of quality information relating to spinal disability. I would strongly recommend these volumes to anaesthetists with an interest in pain management.

There is plenty for the spinal surgeon; there is little for the spinal anaesthetist except for one chapter on anaesthesia and postoperative pain management. Issues are aired in the most general of terms. Cord monitoring is covered briefly and the Stagnara wake-up test is described. The concept of the surgeon giving advance notice of 30–45 min assumes a degree of temporal awareness that is unlikely in most orthopaedic surgeons. Surgery of the paediatric spine is not within the scope of the book and so the anaesthetic challenges relating to this are quite reasonably not covered

The invited authors of chapters are international experts, mainly American. Some differences in indications for surgery are apparent and fascinating. An example would be surgery for sciatica occurring at 3–4 weeks in America rather than the more traditional 6 weeks to 6 months in the UK.

This is a high quality, comprehensive, multi-author text that all medical libraries should possess as a standard reference for disorders of the axial skeleton. Individuals with a specific interest in the adult spine may well wish to have their own copy.

*P. Sell*

*Clinical Notes for the FRCA.* C D DEAKIN Published by Churchill Livingstone, Edinburgh. Pp. 308; indexed; illustrated. Price £17.50

This book has been written as a revision aid for candidates preparing for the final FRCA examination. On the whole it is written in a lecture notes format supplemented with bulleted lists, tables and good illustrations.

The book is divided into 12 chapters. The first three cover the problems of anaesthetizing patients with cardiac, respiratory or neurological disease. The next two chapters are titled "other systems" and "metabolism". These cover a range of subjects, including anaesthesia for all the major surgical specialties and the anaesthetic considerations of particular diseases, including diabetes, obesity and phaeochromocytoma. The next chapter on "miscellaneous" topics is a pot pourri of subjects from anaesthesia for Jehovah's Witnesses to resuscitation, including a brief section on statistics. Additional chapters cover intensive care, obstetrics and paediatric anaesthesia, pain, general pharmacology and equipment Each chapter is supplemented by references which direct the reader to the most recent reviews or textbook chapters which cover the subjects in more detail. The final chapter contains summaries of the most recent national reports of interest to anaesthetists, including NCEPOD and the Confidential Enquiries into Maternal Deaths.

Personally, I liked this book; it is well written, concise and full of useful information. This is not a book for the beginner or for someone who has not read any other textbooks covering anaesthetic specialties. However, it is an extremely useful revision aid, not to be read from cover to cover, but to be dipped into as a quick and portable reference. Although it is more than 300 pages long it fits easily into a briefcase or handbag and is very competitively priced. I am sure it will become a favourite of many trainees.

*A. Ogilvy*

*Anatomy for Anaesthetists*, 7th Edn. H. ELLIS AND S. FELDMAN. Published by Blackwell Science, Oxford. Pp. 374; indexed; illustrated. Price £59.50.

Any book that reaches its seventh edition in less than 25 yr is clearly successful and this is one of the classic books related to anaesthesia to have been produced in modern times. It presents regional anatomy in a manner and sequence that is entirely appropriate to our specialty, and the text, although relatively brief and lacking some detail, is informative and relevant. The illustrations continue to be superb and an object lesson in what can be achieved with clear line diagrams supplemented by carefully thought out shading and minimal use of colour. A superficial examination of the volume suggests that the original drawings from the early editions continue to be used, but I note that they have been re-drawn and this has given them a freshness that prevents the book from looking dated. The volume is nicely produced and I am sure that many anaesthetists will continue to feel that it is an essential component of a personal library.

However, I have some concerns. *Anatomy for Anaesthetists* has always worked well as a source of information on the anatomy that is relevant to our specialty, but it does less well when it strays towards the clinical implications of that anatomy. The unfortunate illustration in the sixth edition that showed a laryngeal mask airway with the concave curvature of the cuff facing posteriorly has been modified but it still does not portray the airway accurately. This may not be of great clinical significance, but there are some much more unfortunate illustrations relating to peripheral nerve blocks. This is particularly true of the section relating to brachial plexus block. If the example of the illustrations was to be followed a pneumothorax would almost be guaranteed and this is most unfortunate given that many trainees are advised to learn their anatomy from this book. My feeling is that the authors should restrict themselves to describing the relevant anatomy (with which they are clearly very familiar) and leave descriptions of clinical block techniques to others. There is significantly more to regional anaesthesia than anatomy, although it would be helpful if there were more descriptions of the fascial planes and sheaths that are encountered during block needle insertion at many sites.

At nearly £60 it is relatively expensive compared with more modern texts of anatomy which base their illustrations on modern imaging technique such as computed tomography and magnetic resonance imaging. However, I feel that the simple line diagram when executed correctly conveys the essence of anatomy which otherwise can be lost in a mass of detail. I just wish that the authors would confine themselves to anatomy.

*J. A. W. Wildsmith*

*Essays on the History of Anaesthesia. International Congress and Symposium Series 213.* A. M. BARR, T. B. BOULTON AND D. J. WILKINSON (eds). Published by The Royal Society of Medicine Press, London. Pp. 226; indexed; illustrated. Price £15.50.

The History of Anaesthesia Society first met in 1986, and now has a membership in the region of 500. Members of the society enjoy a limited circulation booklet containing the proceedings of each meeting. These are useful to keep, but they are not indexed, and the quality of production, although quite satisfactory for the original purpose, is of a modest standard. This new collection of essays represents papers presented to the society in the period 1986–1989. The editors have made a selection, so that the book does not replace the proceedings. Some of the papers have been revised and updated with new illustrations, but it is not clear to what extent or why this was done. Some papers cover a wide scope, while others relate to what are very minor topics. All are nicely presented and are an enjoyable read. I am glad the editors have undertaken this task. Not only is the work a useful contribution to the history of medicine, but for many of us there are papers by and recollections of friends and colleagues who have died since the History of Anaesthesia Society was formed. One hopes this volume is indeed the first of a series.

——, Sternomental distance as predictor of difficult laryngoscopy, Farmery, A D., (*C*) 626
——, Sternomental distance as predictor of difficult laryngoscopy, Gouws, E., *et al.*, (*C*) 626–627
——, Use of a photographic method to compare rigid laryngoscopy techniques, Groom, P., *et al.*, (*ARS*) 466P
**Liver, blood flow,** Effects of desflurane and isoflurane on splanchnic microcirculation during major surgery, O'Riordan, J , *et al.* 95–96
**Liver, function,** Hepatocellular integrity after inhalation anaesthesia, Ray, D C , *et al* , (*C*) 772–773
——, Hepatocellular integrity after inhalation anaesthesia, Tiainen, P., *et al.*, (*C*) 773
**Liver, hepatotoxicity,** Hepatocellular integrity after inhalation anaesthesia, Ray, D. C., *et al.*, (*C*) 772–773
——, Hepatocellular integrity after inhalation anaesthesia, Tiainen, P., *et al.*, (*C*) 773
**Liver, transplantation,** Use of heparinase modified thrombelastography in liver transplantation, Harding, S. A., *et al.* 175–179
**Lung, adult respiratory distress syndrome,** Effect of exogenous nitric oxide and superoxide on interleukin-8 from human polymorphonuclear leucocytes, Cuthbertson, B. H., *et al* 714–717
——, Extracorporeal membrane oxygenation for transport of hypoxaemic patients with severe ARDS, Rossaint, R., *et al* 241–246
**Lung, bronchus,** *In vivo* assessment of droperidol-induced bronchial relaxation in dogs using a superfine fibreoptic bronchoscope, Otomo, N , *et al.* 579–582
——, Measurement of bronchodilatation using a superfine fibreoptic bronchoscope, Otomo, N , *et al.* 583–585
**Lung, damage,** Effect of exogenous nitric oxide and superoxide on interleukin-8 from human polymorphonuclear leucocytes, Cuthbertson, B. H , *et al.* 714–717
——, Pancuronium increases pulmonary arterial pressure in lung injury, Du, H , *et al.*, (*e*) 233
**Lung, intravascular pressure,** Pancuronium increases pulmonary arterial pressure in lung injury, Du, H., *et al* , (*e*) 233
**Lung, respiratory resistance,** Detection of inspiratory resistive loads after anaesthesia for minor surgery, Drummond, G. B., *et al.* 308–310
**Lung, shunting,** "Best" PEEP during one-lung ventilation, Inomata, S., *et al.* 754–756

**Malignant hyperthermia,** Can enoximone trigger malignant hyperthermia? Enright, S M., *et al.*, (*ARS*) 460P
——, Inositol 1,4,5-trisphosphate in blood and skeletal muscle in human malignant hyperthermia, Wappler, F., *et al.* 541–547
**Measurement techniques, anisotropy,** Anaesthetic potency of inhalation agents is independent of membrane microviscosity, Norman, R. I., *et al.* 290–295
**Measurement techniques, calorimetry,** Metabolic effects of i v. propacetamol, metamizol or external cooling in critically ill febrile sedated patients, Poblete, B , *et al.* 123–127
**Measurement techniques, cardiac output,** Validation of thoracic electrical bioimpedance as a porcine research tool, Broomhead, C. J., *et al.* 323–325
**Measurement techniques, Doppler,** Haemodynamic conditions enhancing gas embolism after venous injury during laparoscopy: a study in pigs, Bazin, J. E., *et al.* 570–575
**Measurement techniques, Doppler echocardiography,** Perioperative use of the oesophageal Doppler probe (ODM II) on a patient scheduled for transmyocardial revascularization, Djaiani, G., *et al* 760–761
**Measurement techniques, electrophysiology,** Changes in the early cortical auditory evoked response during hypothermia, Poplar, C. C., *et al.*, (*ARS*) 465P
**Measurement techniques, extraduroscopy,** The lumbar extradural structure changes with increasing age, Igarashi, T., *et al* 149–152
**Measurement techniques, flow cytometry,** Flow cytometry, Galley, H. F., *et al.*, (*C*) 227
——, Flow cytometry, Heine, J., *et al* , (*C*) 227–228
**Measurement techniques, inductance plethysmography,** Discriminating information in uncalibrated respiratory inductance plethysmography, Black, A., *et al* , (*ARS*) 471P
**Measurement techniques, magnetic resonance imaging,** A study of the anatomy of the caudal space using magnetic resonance imaging, Crighton, I M., *et al.* 391–395
——, Anatomical configuration of the spinal column as determined by magnetic resonance imaging, Hirabayashi, Y., *et al.*, (*C*) 339
——, Effects of the pregnant uterus on the extradural venous plexus in the supine and lateral positions, as determined by magnetic resonance imaging, Hirabayashi, Y., *et al.* 317–319
**Measurement techniques, near infrared spectroscopy,** Comparison of the immediate effects of induction of anaesthesia with etomidate, propofol and thiopentone on cerebral haemodynamics, Lovell, A. T., *et al.*, (*ARS*) 473P
——, Non-invasive measurement of cerebral blood flow, Gupta, A. K., *et al.*, (*C*) 774–775
——, Non-invasive measurement of cerebral blood flow, Hill, S. A., (*C*) 774
——, Non-invasive measurement of cerebral blood flow, Williams, D., (*C*) 774
——, Non-invasive measurement of cerebral blood volume in volunteers, Gupta, A. K., *et al.* 39–43
——, Non-invasive measurement of cerebral blood volume in volunteers, Gupta, A. K., *et al* , (*e*) 486
——, Oscillations in arterial saturation implications for the measurement of cerebral blood flow with near infrared spectroscopy, Lovell, A. T , *et al* , (*ARS*) 463P

**Measurement techniques, oesophageal Doppler,** Assessment of cardiovascular changes during laparoscopic hernia repair using oesophageal Doppler, Haxby, E. J., *et al.* 515–519

**Measurement techniques, oximeters,** Validation of pulse oximetry for monitoring of hypoxaemic episodes in the late postoperative period, Stausholm, K., *et al.* 86–87

**Measurement techniques, partial pressure,** A new method for measurement of anaesthetic partial pressure in blood, Smith, M. A., *et al.* 449–452

**Measurement techniques, thermodilution,** Validation of thoracic electrical bioimpedance as a porcine research tool, Broomhead, C. J., *et al* 323–325

**Measurement techniques, thoracic electrical bioimpedance,** Validation of thoracic electrical bioimpedance as a porcine research tool, Broomhead, C. J., *et al.* 323–325

**Measurement techniques, thrombelastography,** Effect of progressive haemodilution with hydroxyethyl starch, gelatin and albumin on blood coagulation, Egli, G. A., *et al.* 684–689

——, Use of heparinase modified thrombelastography in liver transplantation, Harding, S. A., *et al.* 175–179

**Measurement techniques, tomography,** Regional cerebral blood flow (SPECT) during anaesthesia with isoflurane and nitrous oxide in humans, Reinstrup, P., *et al.* 407–411

**Measurement techniques, voltammetry,** Changes in extracellular brain ascorbate in rat striatum in response to administration of non-volatile anaesthetic agents, Miele, M., *et al.* 588–590

**Medico-legal, informed consent,** Audit of patients' attitudes to consent to clinical trials in anaesthesia, Montgomery, J. E., *et al.*, (*ARS*) 457–458P

**Membrane, lipid bilayer,** Volatile anaesthetic effects on calcium conductance of planar lipid bilayers formed with synthetic lipids or extracted lipids from sarcoplasmic reticulum, Andoh, T., *et al* 66–74

**Memory,** Absence of memory for intraoperative information during surgery under adequate general anaesthesia, Russell, I. F., *et al.* 3–9

**Metabolism, glucose,** Effects of clonidine on the pituitary hormonal response to pelvic surgery, Lyons, F. M., *et al.* 134–137

**Metabolism, inositol phosphate,** Inositol 1,4,5-trisphosphate in blood and skeletal muscle in human malignant hyperthermia, Wappler, F., *et al.* 541–547

**Metabolism, lipids,** Effect of lipid and propofol on oxidation of haemoglobin by reactive oxygen species, Stratford, N., *et al.* 320–322

**Model, computer,** A model of the electrocortical effects of general anaesthesia, Sleigh, J W., *et al.* 260–263

**Model, computer simulation,** Development of a computer system for prediction of difficult laryngoscopy, Gillies, D. F., *et al.*, (*ARS*) 466–467P

——, Effect site modelling of combined fentanyl bolus and alfentanil infusion, Rushton, A. R. A., *et al.*, (*ARS*) 461–462P

——, Inaccurate reporting of simulated critical anaesthetic incidents, Byrne, A. J., *et al.* 637–641

——, Partial liquid ventilation—turning back a PAGE on evolution, Kelly, K. P., (*E*) 1–2

**Ventilation, hypoxic response**, Influence of 0.2 minimum alveolar concentration of enflurane on the ventilatory response to sustained hypoxia in humans, Nagyova, B , *et al* 707–713

**Ventilation, intermittent positive-pressure**, Performance of vaporizers in circle systems, Wright, D., *et al.*, (*ARS*) 463–464P

**Ventilation, mechanical**, Are there new solutions to old problems with weaning? Shneerson, J. M., (*E*) 238–240

——, "Best" PEEP during one-lung ventilation, Inomata, S., *et al.* 754–756

——, Extracorporeal membrane oxygenation, a favourable outcome? Peek, G. J., *et al.*, (*E*) 235–237

——, Extracorporeal membrane oxygenation for transport of hypoxaemic patients with severe ARDS, Rossaint, R., *et al.* 241–246

**Ventilation, one-lung**, "Best" PEEP during one-lung ventilation, Inomata, S., *et al* 754–756

**Ventilation, partial liquid**, Partial liquid ventilation—turning back a PAGE on evolution, Kelly, K. P., (*E*) 1–2

**Ventilation, positive end-expiratory pressure**, "Best" PEEP during one-lung ventilation, Inomata, S , *et al.* 754–756

——, Only a small increase in end-expiratory pressure after cardiac surgery in Manchester, Fletcher, R , *et al.*, (*ARS*) 471P

**Ventilation, spontaneous**, Coupling of spontaneous ventilation to heart beat during benzodiazepine sedation, Galletly, D C., *et al.* 100–101

**Vomiting, antiemetics**, Meta-analytic comparison of prophylactic antiemetic efficacy for postoperative nausea and vomiting: propofol anaesthesia *vs* omitting nitrous oxides *vs* total i.v. anaesthesia with propofol, Tramèr, M., *et al.* 256–259

——, Propofol anaesthesia and postoperative nausea and vomiting: quantitative systematic review of randomized controlled studies, TRAMÈR, M., *et al.* 247–255

**Vomiting, incidence**, Intraoperative gut hypoperfusion may be a risk factor for postoperative nausea and vomiting, GAN, T. J., *et al.*, (*C*) 476

——, Intraoperative gut hypoperfusion may be a risk factor for postoperative nausea and vomiting, GREBENIK, C. R., (*C*) 476

——, Meta-analytic comparison of prophylactic antiemetic efficacy for postoperative nausea and vomiting: propofol anaesthesia *vs* omitting nitrous oxides *vs* total i.v. anaesthesia with propofol, TRAMÈR, M., *et al.* 256–259

——, Propofol anaesthesia and postoperative nausea and vomiting: quantitative systematic review of randomized controlled studies, TRAMÈR, M., *et al.* 247–255

**Vomiting, nausea**, Intraoperative gut hypoperfusion may be a risk factor for postoperative nausea and vomiting, GAN, T. J., *et al.*, (*C*) 476

——, Intraoperative gut hypoperfusion may be a risk factor for postoperative nausea and vomiting, GREBENIK, C. R , (*C*) 476

——, Meta-analytic comparison of prophylactic antiemetic efficacy for postoperative nausea and vomiting: propofol anaesthesia *vs* omitting nitrous oxides *vs* total i.v anaesthesia with propofol, TRAMÈR, M., *et al.* 256–259

——, Propofol anaesthesia and postoperative nausea and vomiting: quantitative systematic review of randomized controlled studies, TRAMÈR, M., *et al.* 247–255

**Vomiting, nausea, surgical factors**, Intraoperative gut hypoperfusion may be a risk factor for postoperative nausea and vomiting, GAN, T. J., *et al.*, (*C*) 476

——, Intraoperative gut hypoperfusion may be a risk factor for postoperative nausea and vomiting, GREBENIK, C. R., (*C*) 476
